SUBDIAPHRAGMATIC ABSCESS IN CHILDREN*

WILLIAM E. LADD, M.D.,† AND HENRY SWAN, M.D.‡

BOSTON

A RECENT experience with the problem presented by a subdiaphragmatic abscess complicating the postoperative course of a three-year-old boy with a ruptured appendix has led us to review the cases previously seen at the Children's Hospital with this condition. As a late complication of intra-abdominal sepsis in children, subphrenic abscess ranks as a rare but important offender. It may occasionally occur as the only site of intra-abdominal infection, in which case its recognition may be difficult. It is generally agreed that the mortality of untreated subdiaphragmatic abscess is between 90 and 100 per cent. Clearly early diagnosis and rational treatment are imperative under such threatening circumstances. Fourteen patients have been seen at the Children's and Infants' hospitals in whom an abscess in the subdiaphragmatic space has been recognized. Eleven of these were treated surgically, with 1 death; the other 3 had cases of fulminating infection and died, and at post mortem a subphrenic abscess was found as one among multiple manifestations of generalized sepsis.

INCIDENCE

Subphrenic abscess is encountered less frequently in infants and children than in adults. Thus, in Gatewood's¹ 41 cases, only 1 patient was a child, aged eight. Brown² reports 4 patients under ten years. Ireland³ presents 6 patients under twelve. In the cases, both collected and personal, presented by Ochsner and DeBakey⁴ the youngest age group considered was from nine to nineteen. Apparently none of their patients were younger than nine.

The present series comprises 14 patients under eleven years of age, 6 of whom were less than two years old. There were 9 boys and 5 girls. All but one of the patients were of the white race.

The incidence of subphrenic abscess as a complication of acute appendicitis is not high, even though one of the most frequent causes of all subphrenic abscesses is a suppurative lesion of the appendix. In 15,000 collected cases⁴ of acute appendicitis, approximately 0.9 per cent suffered this complication. The incidence in children seems to be even lower. At the Children's Hospital in recent years, 860 children with acute appendicitis have been seen; 3 patients subsequently developed subphrenic abscess, an incidence of roughly 0.3 per cent.

PATHOGENESIS

The mode of infection of the subphrenic spaces in our series (Table 1) is quite varied, and sug-

TABLE 1. *Mode of Infection in Subdiaphragmatic Abscess.*

PATHOGENESIS	No. of Cases
Following intra abdominal sepsis	9
Ruptured appendix	5
Primary peritonitis	2
Rupture of ileum	1
Liver abscess	2
Metastatic from a distant focus	4
Upper respiratory infection	2
Otitis media	1

gest that several different mechanisms may be at work in the introduction of infection into those regions.

In the experience of all observers a suppurative appendix is the commonest preceding event. This was true in our series, with 5 patients (36 per cent) falling into this category. It has been thought by many that the course of the infection is by direct extension up the right gutter. If this were true, one would expect the right posteriosuperior space to be most frequently involved, as is indeed the case in the large collected series of Ochsner and

lead to a more rational operative approach. However, in children this is less readily done than in older patients. In the child, the signs of the underlying infection may extend so widely that they overlap anatomic regions, thus leaving the examiner in some doubt concerning the exact space primarily involved.

In this series, the abscesses were localized as follows: right anterosuperior, 8 cases; right posterior, 3 cases; and right inferior, left superior and left anteroinferior, 2 cases each. It will be seen that the right anterosuperior space was by far the most frequently involved space. This is in distinct contrast to the published incidence of a large series of collected cases,⁴ where the right posterosuperior space was most commonly involved. For this, we have no anatomical or etiologic explanation.

CLINICAL ASPECTS

The symptomatology of subdiaphragmatic abscess as presented by our patients has shown considerable variation, but it appears that, in children at least three different types of clinical picture are encountered. These roughly parallel the different modes of origin of the infection as discussed above.

The first group comprise those cases in which the subphrenic infection is merely part of a wide-spread intra-abdominal suppurative process. In these patients there is a rather abrupt onset of what appears to be a severe infectious disease. The constitutional signs of fever, anorexia, prostration, malaise and tachycardia are associated with some evidence of intra-abdominal involvement, such as vomiting, abdominal pain, diarrhea, tenderness, spasm and decrease or absence of intestinal peristalsis. The course of the disease tends to be fulminating, the patient dying within a few days from the onset. In 3 of our patients, this type of course was observed. One had a primary peritonitis associated with empyema and septicemia, another had peritonitis secondary to a ruptured ileum (above an atresia), and the third had a septic thrombophlebitis of the umbilical vein with peritonitis, multiple liver abscesses, bronchopneumonia and septicemia. In all these patients, the small subphrenic abscesses found post mortem represented but a minor and relatively insignificant part of a fulminating generalized sepsis. None were recognized clinically before death, but such recognition could have in no way altered their course.

The second group, wherein the subphrenic infection complicates the course of acute ruptured appendicitis, is the type most commonly seen. The clinical syndrome has been thoroughly described in the literature, and the progress of the

infection in children seems to differ in no significant way from that observed in adults. The persistence of the evidences of infection as demonstrated by continued fever and tachycardia, malaise and elevation in the number of leukocytes, which is unexplained by the abdominal, rectal or urinary findings or by the condition of the wound, suggests the walling off of an infectious process in some other area. The localizing signs in our experience have been varied. Tenderness along the course of the twelfth rib or over the liver is usually present. We have, however, been unable to distinguish between anterior-space and posterior-space infections by this means. Spasm in the right upper quadrant of the abdomen, or even a palpable mass, is frequently present. Pleural effusion, as suggested by dullness or flatness to percussion, diminution in tactile fremitus and distant breath sounds, is usually found. Indeed, the problem most commonly resolves itself into a differential diagnosis between a subphrenic infection and a pulmonary complication. In this distinction the roentgenologic findings are of considerable importance. In our series the most consistent signs observed were elevation and fixation of the diaphragm. These findings have been emphasized by Grainger,⁸ Lewald,⁹ Pancoast¹⁰ and others. In 2 patients only was air observed beneath the diaphragm. Thus, when present, gas is of diagnostic significance, but it is usually not present or is a late finding, and hence its absence is of no significance. Obliteration of the costophrenic angle with a diffuse haziness suggesting pleural effusion is frequently present. In 3 of our patients, however, the diaphragms were described as normal in position, contour and motion, and no fluid was observed in the pleural space. Thus, the roentgenologic examination may be of aid, but no observable abnormality may be present, and no commonly found variation from normal is pathognomonic.

The third group, perhaps the most interesting and difficult to diagnose, comprises those cases in which the subphrenic abscess is metastatic and is at once the chief or only disease present and the cause of the patient's admission to the hospital. These patients have a history of upper respiratory infection, otitis media or recurrent superficial staphylococcal infection. This is followed some days later by the vague and insidious onset of mild malaise and anorexia, associated with low-grade pyrexia. These symptoms persist, and there begin occasional attacks of abdominal pain. These rather mild symptoms gradually increase over a period of one to three months until the patient is finally brought to the hospital because of the appearance of a mass in the upper abdo-

DeBakey.⁴ In our few cases, however, the anterior space was more frequently involved than the posterior one following appendicitis, suggesting that some other mechanism may have been present. The possibility of lymphatic extension has been emphasized by Truesdale.⁵ We have routinely used Fowler's position in all patients with intra-abdominal suppuration, theoretically to prevent upward extension of the process into the subdiaphragmatic region. If lymphatic extension is the mechanism at fault, this seems to be unnecessary, but in the light of our relatively low incidence of subphrenic complications and until this matter has become more clearly settled, we see no reason to discontinue the use of Fowler's position in these patients.

Other intra-abdominal conditions that have been stressed in the literature as leading to subphrenic abscess are diseases of the stomach and duodenum (ruptured peptic ulcer) and diseases of the liver and gall bladder (cholecystitis and cholelithiasis). These conditions are extremely rare in childhood, and none of our patients can be classified in this category. Two patients, however, suffered from abscesses of the liver that broke into the subphrenic space. One of these had ulcers of the rectum leading to a septic pyelophlebitis and multiple liver abscesses and thence to a left antero-inferior subphrenic abscess. The other patient's liver abscesses derived from a septic thrombosis of the umbilical vein, ultimately at the age of three weeks—leading to a right inferior abscess. Both these patients died.

In 4 of our patients the infection appears to have been seeded by the blood stream. One patient had recurrent hordeola and subsequently developed a large right anterior abscess from which a hemolytic *Staphylococcus aureus* was cultured.

Another large abscess followed one month after an attack of suppurative otitis media. Two more were preceded by severe upper respiratory infection. The exact site in which the infection lodges in these cases is not clear. It seems unlikely that the metastatic infection begins as a localized inflammation of the peritoneum bordering the subphrenic spaces. It is probable that the organisms gain a foothold in the liver, forming an abscess or abscesses that subsequently break through adjacent subdiaphragmatic spaces, thus subsequently more extensive process on.

trauma was the initiating factor. This six-year-old boy, was struck on the right ? automobile. Shortly thereafter there ? of intra-abdominal hemorrhage as-ld shock. This was treated con- id sedation in another

hospital. On the twelfth day the patient became febrile and complained of increasing right-sided pain and also pain in the right shoulder. Subsequently, we drained a right anterior abscess containing foul pus with a fecal odor from which a colon bacillus was cultured. It was thought that the original trauma was rupture of the liver with hematoma, but in the light of the subsequent bacteriology it is probable that some portion of the alimentary canal was also ruptured at the time of the accident, thus releasing the organisms that established the subsequent abscess.

ANATOMICAL LOCALIZATION

Since publication of the anatomical descriptions of Martinet⁶ and Barnard,⁷ it has become a common practice to define the subdiaphragmatic region as the space bordered above by the diaphragm and below by the transverse mesocolon. Thus, the abscesses occurring just below the liver, as well as those occurring between the liver and the diaphragm, are included within the boundaries of the subphrenic region.

The liver may be regarded as dividing this broader area into two regions, the suprahepatic and infrahepatic; each of these, in turn, is further divided by anatomic attachments into three spaces, making six in all. Beneath the diaphragm, the falciform ligament suspending the liver from that structure divides the suprahepatic area into essentially equal-sized right and left spaces. On the left, there is but a single superior space, but on the right the lateral reflexion of the coronary ligament divides the right space into a small posterior one and a large anterior one. Conversely, in the infrahepatic region, which is divided into right and left spaces by the round ligament and the ligament of the ductus venosus, there is but a single right inferior space, whereas on the left the gastrohepatic ligament divides the area into a posterior space, which is merely the upper portion of the lesser omental cavity, and a larger anterior space, between the liver and the stomach.

These divisions are present in infancy. No apparent anatomic variation from the adult is present in childhood to explain the relative rarity of infection of these spaces in children, with one possible exception. The suspensory ligaments of the liver are comparatively tighter and shorter in the young than in the old, thus tending to hold the liver more firmly upward against the diaphragm and squeezing closed the suprahepatic spaces.

Thus, there are six anatomically discrete intra-peritoneal subphrenic spaces in which abscess formation can occur. Clearly, anatomical knowledge of these areas will lead to more exact clinical localization of such infections, which in turn will

phragmatic retroperitoneal (extraserous) approach is clearly the procedure of choice.

In anterior-space infections, particularly in cases in which a mass is present, drainage can be effected extraserously by direct approach through the anterior abdominal wall. Incision may be either parallel to the costal margin or a short, vertical, high, paramedian one. The adhesions existing between the abscess and the anterior peritoneum allow drainage through them without soiling of the uninvolved general peritoneal cavity.

For the posterior-space infections, the so-called "retroperitoneal approach" was described by Ochsner and Graves¹¹ and has been utilized by Faxon¹². This involves resecting the twelfth rib and incising horizontally at the level of the spinous process of the first lumbar vertebra. The peritoneum is then dissected off the undersurface of the diaphragm until the cavity is reached.

In children, the exact anatomic localization, whether anterior or posterior, may be quite indefinite. Furthermore, this approach, although favorable for the superoposterior infections most frequently encountered in adults, is inadequate or at best unduly difficult if the infection lies in the anterior portion of the suprahepatic space, as is most frequently the case in children. We have therefore adopted and used with success a slightly different type of retroperitoneal approach. In this procedure, incision is made parallel to and just below the costal margin in the midaxillary line. The muscle layers are incised until the peritoneum is reached. Then, with blunt dissection, the peritoneum is peeled away from the undersurface of the diaphragm until the firm pyogenic wall is reached, when a finger is inserted in the abscess. Drainage tubes are inserted and the wound is closed with chromic-catgut sutures to the drain. This approach, although similar to that of Ochsner and Graves in that it is entirely extraserous, differs from it in that the incision is slightly lower and more lateral. The infection of both the anterior and posterior spaces can be readily drained, and the twelfth rib is spared.

In our series, 11 patients underwent operation for drainage of a subphrenic abscess, with 1 death—a mortality of 9 per cent. Of these patients, 5 had direct incisions into anterior-space infections, so that the abscess could be drained without opening the peritoneal cavity. The single death in this group occurred in a patient with phlebitis and multiple liver abscesses. Five other patients underwent a transthoracic approach. In 2, the pleural cavity was soiled, with resultant empyema; in 1, the peritoneum was opened, with exacerbation of the peritoneal infection; in 1, the abscess was

not found (perhaps fortunately) and was subsequently drained by the extraserous approach; whereas in only 1 was drainage satisfactorily accomplished without complications. Two patients were drained by the extraserous approach, one primarily and one secondarily after an unsuccessful transthoracic attempt. Both healed rapidly without complication.

To summarize, there were 5 cases that had a direct incision and 2 in which the peritoneum was stripped from the diaphragm, making 7 that for practical purposes had an extraserous approach. These patients had a much shorter and better convalescence than did those who had a trans-serous approach.

Thus, our experience with the transthoracic approach is entirely in line with that of Faxon and of Ochsner and his co-workers and has led us to abandon the procedure. Although there were no deaths in this series, the morbidity was high, and we must consider ourselves as enjoying better luck than management in this regard.

SUMMARY

A series of 14 children with subdiaphragmatic abscess is presented.

Although subphrenic abscess is not frequent in children, when present it represents a serious disease, with forbidding mortality if untreated.

Metastatic infection of the subphrenic spaces by way of the blood stream is commoner in children than in adults, and presents a characteristic symptom complex.

Exact preoperative localization of the abscess is more difficult in children than in adults, and anterior-space infections are commoner in adults.

The extraserous approach is by all odds the one of choice. Such a procedure with incision in the midaxillary line just below the costal margin is advocated for use in children.

men, which may be localized on the side of the disease. Usually, some weight loss is present, and mild secondary anemia. Examination reveals a degree or two of fever, tachycardia, an elevation

approach the abscess. In the light of the overwhelming statistical evidence recently presented by Ochsner and DeBakey⁴ and Faxon,¹² it appears that there is no longer any justifiable reason for

FIGURE 1.

Photographs of patient with large subdiaphragmatic abscess secondary to multiple hordcola, showing the right upper quadrant abdominal mass.

of the white-cell count and a diffuse, slightly tender mass in either the left or right upper quadrant, just under the costal margin.

The problem in diagnosis is that presented by an upper abdominal tumor. In 3 of our 4 patients the correct diagnosis was not made until the abscess was found at operation. It is our belief, however, that with such a history in a child with the constitutional signs of a chronic infectious disease and an upper abdominal mass, an accurate preoperative diagnosis can and should be made. Roentgenologic examination may be of corroborative value as in the postappendiceal variety.

TREATMENT

That early and adequate drainage is the correct treatment for subphrenic abscess is generally agreed. Until recent years, however, the best method of approaching these abscesses has been much debated. Three general types of operation have been evolved to solve the difficulties presented by an abscess in as relatively an inaccessible location as is the subphrenic space. These can be classified as transperitoneal, transpleural and extraserous, according to the route used to

using any approach other than the extraserous. The prolongation of the course, the marked increase in the incidence of complications and, above all, the much higher mortality rate associated with both the trans-serous approaches have been amply demonstrated. Thus, Faxon has shown that contamination of an uninvolved serous cavity during operative drainage increases the mortality to a level two and a half times as high as that in cases in which such contamination is avoided. In his series, contamination of a serous cavity carried a mortality of 62 per cent, whereas if neither cavity was contaminated, the mortality was 24 per cent. In the personal cases of Ochsner and DeBakey,⁴ the mortality of trans-serous approach was around 45 per cent, and that of the extraserous approach was in the neighborhood of 10 per cent. The mortality in their large series of collected cases showed similar differences. Surgical rationale and statistical evidence alike demand that only an extraserous route be employed in the drainage of these abscesses. That single or two-stage transthoracic procedures aiming to obliterate the pleural space are deceptively dangerous and fail to protect the pleural cavity is also clearly shown in these statistics. An infradia-

phragmatic retroperitoneal (extraserous) approach is clearly the procedure of choice.

In anterior-space infections, particularly in cases in which a mass is present, drainage can be effected extraserously by direct approach through the anterior abdominal wall. Incision may be either parallel to the costal margin or a short, vertical, high, paramedian one. The adhesions existing between the abscess and the anterior peritoneum allow drainage through them without soilage of the uninvolved general peritoneal cavity.

For the posterior-space infections, the so-called "retroperitoneal approach" was described by Ochsner and Graves¹¹ and has been utilized by Faxon.¹² This involves resecting the twelfth rib and incising horizontally at the level of the spinous process of the first lumbar vertebra. The peritoneum is then dissected off the undersurface of the diaphragm until the cavity is reached.

In children, the exact anatomic localization, whether anterior or posterior, may be quite indefinite. Furthermore, this approach, although favorable for the superoposterior infections most frequently encountered in adults, is inadequate or at best unduly difficult if the infection lies in the anterior portion of the suprahepatic space, as is most frequently the case in children. We have therefore adopted and used with success a slightly different type of retroperitoneal approach. In this procedure, incision is made parallel to and just below the costal margin in the midaxillary line. The muscle layers are incised until the peritoneum is reached. Then, with blunt dissection, the peritoneum is peeled away from the undersurface of the diaphragm until the firm pyogenic wall is reached, when a finger is inserted in the abscess. Drainage tubes are inserted and the wound is closed with chromic-catgut sutures to the drain. This approach, although similar to that of Ochsner and Graves in that it is entirely extraserous, differs from it in that the incision is slightly lower and more lateral. The infection of both the anterior and posterior spaces can be readily drained, and the twelfth rib is spared.

In our series, 11 patients underwent operation for drainage of a subphrenic abscess, with 1 death—a mortality of 9 per cent. Of these patients, 5 had direct incisions into anterior-space infections, so that the abscess could be drained without opening the peritoneal cavity. The single death in this group occurred in a patient with plebitis and multiple liver abscesses. Five other patients underwent a transthoracic approach. In 2, the pleural cavity was soiled, with resultant empyema; in 1, the peritoneum was opened, with exacerbation of the peritoneal infection; in 1, the abscess was

not found (perhaps fortunately) and was subsequently drained by the extraserous approach; whereas in only 1 was drainage satisfactorily accomplished without complications. Two patients were drained by the extraserous approach, one primarily and one secondarily after an unsuccessful transthoracic attempt. Both healed rapidly without complication.

To summarize, there were 5 cases that had a direct incision and 2 in which the peritoneum was stripped from the diaphragm, making 7 that for practical purposes had an extraserous approach. These patients had a much shorter and better convalescence than did those who had a trans-serous approach.

Thus, our experience with the transthoracic approach is entirely in line with that of Faxon and of Ochsner and his co-workers and has led us to abandon the procedure. Although there were no deaths in this series, the morbidity was high, and we must consider ourselves as enjoying better luck than management in this regard.

TIDAL DRAINAGE AND CYSTOMETRY IN THE TREATMENT OF SEPSIS ASSOCIATED WITH SPINAL-CORD INJURIES*

A Study of One Hundred and Sixty-Five Cases

DONALD MUNRO, M.D.†

BOSTON

SEPSIS is one of the most prolific causes of death and unnecessary disability in patients with spinal-cord injuries. Except for an occasional post-operative wound infection, it always originates as the result of inadequate care either of the urinary bladder or of the skin of the back or both. This paper deals with the genitourinary aspect of the problem, and presents my experiences with 165 patients with all levels and types of spinal-cord injury.

An understanding of the changes that take place in the human urinary bladder following a spinal-cord injury is impossible without an equal grasp of the physiology of urination. The classic work of Denny-Brown and Robertson¹ has been confirmed by myself,^{2,3} McLellan⁴ and many others, although some writers, like Langworthy and others^{5,6} do not agree with us in all details. All do agree, however, that the bladder is an organ the fundamental control of which is vested in two reflex arcs whose central connections are located in the sacral segments of the spinal cord. The peripheral part of the first is formed by the parasympathetic nerves in the pelvic plexus, and that of the second by the internal pudic nerve, which is a branch of the sacral plexus. The latter is a somatic nerve, and as such the impulses it carries are subject to voluntary control. There is also a third reflex arc, which comes into play only when the bladder is either anatomically or physiologically denervated. It lies completely within the confines of the bladder wall, is analogous to Auerbach's plexus, and is extremely inefficient. The motor impulses passing over the first two of these reflex arcs are subject to modification by other impulses reaching them by way of the long tracts in the cord and arising in the suprasegmental levels. In addition, the musculature of the bladder wall has a specialized attribute that is known as the stretch reflex. This is a mechanism whereby the individual muscle fibers, in response to the stimulus of having previously been stretched to their limit, retain the choice either of contracting sharply and emptying the bladder—a so-called "emptying contraction"—or of lengthening themselves and thereby in-

creasing the capacity of the reservoir. This stretch reflex allows a hollow organ such as the bladder, intestine or uterus to choose, as it were, between either one of two responses to a single stimulus. It is constantly being invoked in the normal bladder, and the addition of even small quantities of urine to whatever may be already present, regardless of amount, sets up a constant succession of stretch reflexes. Under appropriate circumstances and surroundings, these either turn into emptying contractions or, if the set-up is not suitable for urination, cause distention of the bladder without contraction of its wall and with an increase in its capacity. The impulses that reach the bladder from the brain are entirely inhibitory. They develop because of the dictates of civilization, one's early training, peculiar surroundings and the like, and serve to prevent any given stretch reflex from becoming an emptying contraction in circumstances that are not suitable. As is well known, they may inhibit emptying contractions so successfully as to lead to overstretching and pain and to make catheterization necessary. They are entirely outside of the conscious sphere and may exert a tremendous indirect influence on the life and activity of the individual, but act only to *stop* urination. On the other hand, facilitation of urination is entirely outside of the individual's power. It depends on and occurs only in the presence of an emptying contraction, is totally *segmental* in so far as anatomic connections go, and occurs only because the subject may fail to inhibit an emptying contraction and thus passively permit urination.

Although still disputed, the best evidence at this time seems to be that in man the sympathetic system, so far as the bladder is concerned, has to do *only* with transmission of pain. A series of personal observations made on 12 otherwise normal women who had had complete presacral neurectomies for dysmenorrhea has satisfied me that this statement is true. Cystometric observations made on their bladders before and after the neurectomies showed no change whatsoever in bladder function. It must therefore be concluded that the sympathetic system plays no part in the control of bladder activity. Others have made similar observations, and there can be little doubt that the earlier and more convenient theory of reciprocal para-

*From the Department of Neurosurgery, Boston City Hospital.

†Surgeon-in-chief for and head of the Department of Neurosurgery, Boston City Hospital.

sympathetic-sympathetic control of the bladder must be abandoned.

My first 36 cases of injury to all levels of cord and cauda equina came under my care before Denny-Brown and Robertson¹ had demonstrated in more detail the physiology that I have briefly sketched above. Twenty-six, or 72 per cent, developed major infections of the genitourinary tract. This was despite the use of all the then recognized methods of treating the bladder in these cases. To meet this difficulty the tidal-drainage apparatus was developed in 1935, and to ensure its success a separate cystometer was also constructed.² The former remained unchanged until it was modified by MacNeill and Bowler³ in 1940. By introducing the irrigating fluid directly into the bladder by way of a two-way catheter or a Y tube attached to the outer end of the single catheter while the other arm carried the outflow to the siphon curve and air seal, they enabled efficient irrigation of the bladder to be carried out with each cycle. This method allowed us to demonstrate that irrigation with a weak acid solution was much more effective in controlling bacteriuria than was alkaline potassium permanganate. I accordingly modified our apparatus to conform to MacNeill and Bowler's change and substituted 0.5 per cent acetic acid for 1:30,000 potassium permanganate as the irrigating fluid. This was a distinct step in advance, but the size and lack of transportability of the apparatus were still inconvenient. Furthermore, all attempts to combine the cystometer and tidal drainage into one apparatus failed. Thus, the making of the cystometrograms that were so essential to the successful working of the tidal drainage was neglected because of the trouble involved in sterilizing and setting up two separate pieces of apparatus. With the advent of Canada into the war and the need for transporting Canadian soldiers with spinal-cord injuries from England back to this continent, the problem of the continued use of the tidal-drainage apparatus during the transatlantic crossing was solved first by Stewart⁴ and later by Cone and Bridgers.⁵ They did their work in both England and Canada and have devised two further modifications of my apparatus, each of which is portable and also acts as a combined tidal-drainage apparatus and cystometer.

For the air seal Stewart substituted a capillary tube (Fig. 1), connecting this to the bladder outlet by way of a Carrel-Dakin glass connector with three side openings and one end opening. A manometer tube marked with graduations in any suitable way is attached to one side opening, the capillary tube to the second, and the end of the siphon tube to the third. The manometer tubing

is kept closed by a clamp on the rubber connection when the apparatus is used for tidal drainage, and is opened and used as a cystometer when cystometrograms are to be made. I have retained

FIGURE 1. Munro's Tidal-Drainage Apparatus, as Modified by MacNeill and Bowler and by Stewart.

MacNeill and Bowler's modification with this apparatus, although neither Stewart in his model nor Cone and Bridgers in theirs did so originally. Both their apparatus work despite the fact that, during siphonage, air bubbles in through the capillary tube. The bubbles are so small, however, that they do not break the siphon until the bladder is empty. We have found, and Cone and Bridgers have warned, that care must be taken to see that the column of fluid in the descending arm of the siphon is of sufficient length to make enough negative pressure to empty the bladder. For various reasons, chiefly connected with ease of cleaning and comprehension on the part of nurses and house officers, I prefer and now use in all cases the apparatus as modified by MacNeill and Bowler and by Stewart. The materials required to make it are a 1000-cc. irrigator bottle with a bottom opening, an airtight Murphy dropper, two compression clamps, a glass Y tube, a piece of

at a time are probably not reliable. They cannot approximate in any way the conditions that exist when the bladder is being filled by the kidneys, and therefore conclusions based on such observations will of necessity be wrong. Neither should any dependence be placed on having the patient note when he first has a desire to void, nor is any information to be gained from it. In the first place, a conscious desire to void, if the patient is out of babyhood, will depend on his surroundings and a psychologic adjustment to them that

Diagram illustrating a graduated container (top) with a stopcock (middle) and an air tight dropping funnel (bottom).

FIGURE 3. *The Munro Cystometer.*

differs in every patient and from time to time in the same patient. Not to recognize this is to fail to realize that civilization has set up certain standards of personal hygiene that at least in Anglo-Saxon countries are still in force. Conclusions drawn from information concerning when the patient has his first desire to void point not to the degree and kind of bladder function that he has, but rather to his ability to adjust himself to urinating in unusual circumstances.

The figures that follow are the results of studies made with the help of these various types of apparatus on 165 patients with injuries of the spinal cord and cauda equina. They include ex-

amples of edema, hematomyelia, contusion and partial or complete transection of all levels of the cord; stab wounds and bullet wounds of the cord and concussion from bullet wounds of the bony canal without direct cord involvement; compression by dislocated vertebrae, misplaced bone fragments and extra or subdural clots; and all ages of

Tidal Drainage Necessary But Not Used

Tidal drainage was needed but not used in 37 patients, including the 36 patients mentioned above as having been cared for before the apparatus had been invented (Table 1). Twenty-three had cervical injuries, 11 dorsolumbar, and 3 cauda equinal. Twenty-six patients died, all but 1 in the

adhesive constriction of the cauda equina by organized blood clots. One hundred injuries were in the cervical region; 41 involved the dorsolumbar and sacral cord, and 24 the cauda equina. The mortality of the group as a whole was 43 per cent and varied from a high point of 56 per cent in the dorsolumbar group through 46 per cent in the cervical to a low point of 8 per cent in the cauda equinal patients. The fact that the highest death rate was associated with the dorsolumbar cord injuries and not, as might be expected, with the cervical ones should not be overlooked.

METHOD OF TREATMENT

Tidal Drainage Unnecessary

Twenty-seven patients had normal function of their genitourinary apparatus by the time they arrived in the hospital, despite the fact that they presented unmistakable clinical evidence of damage to the spinal cord or cauda equina. Seventeen had cervical injuries; 1 was dorsolumbar, and 9 cauda equinal. Among them were 1 case with a fractured atlas, 2 with stab wounds, 2 with radiculitis in addition to cord injury and 1 each with an arachnoidal hemorrhage and chronic arachnoiditis. There were no deaths and no complications except for a bedsore that developed in a syphilitic patient. This healed promptly on anti-syphilitic therapy.

hospital. Ten of these died within forty-eight hours of the receipt of the injury and consequently did not live long enough to develop sepsis. Seven died without evidence of genitourinary or other major sepsis. In 9 others, sepsis was present and unhealed at the time of death, an incidence of 56 per cent among those who survived the first forty-eight hours. Eleven patients were discharged alive. These included 3 with cervical, 7 with dorsolumbar and 1 with a cauda equinal injury. Three patients had major sepsis during their hospital stay. In one the sepsis was in the genitourinary tract only and in another this was combined with a septic bedsore, in the third case the source of sepsis was a bedsore alone. There were 8 patients who had no sepsis—4 with cervical and 2 each with dorsolumbar and cauda-equinal injuries. This is an incidence of sepsis among the living of 27 per cent.

When these figures are combined, it appears that 12 (44 per cent) of 27 patients who lived long enough to need but did not have treatment by tidal drainage had major sepsis at the time of death or discharge. This sepsis either involved the genitourinary tract or had its source in a bedsore or both. This incidence compares with the 72 per cent of similar major infections that developed in 36 patients during the course of their

stay. Both figures indicate the tremendous part played by the untreated genitourinary tract in causing death and disability in spinal-cord lesions

bedsores that had not healed by the time they died. One of these was directly traceable to neglect on the ward. The other five were present in spite of

under what would otherwise be favorable circumstances.

Tidal Drainage Necessary and Used

Tidal drainage was necessary and used in 101 patients. Sixty had cervical, 29 dorsolumbar and 12 cauda-equinal injuries (Table 2). Forty-five patients died—all in the hospital. Of these, 12 died within forty-eight hours of the infliction of the injury and before they had time to develop any major sepsis.

Thirty-three patients developed major sepsis during their stay on the ward. Sixteen were discharged dead—a mortality of 50 per cent. In 9 of these patients neither the death nor the sepsis had any connection with the use of the tidal-drainage apparatus. This group was made up of 3 cases of ruptured urethra from instrumental perforation, 1 of ruptured bladder produced in the course of a lithopaxy, 1 of bed sore that developed at the site of a bruise sustained at the time of the injury and 4 of extensive bedsores that were already present at the time the patient came under my care. One of the last occurred in a patient who subsequently died of a ruptured urethra. In addition, 1 patient died as the result of a peritonitis caused by the rupture of an enterostomy fistula that had been made in order to treat the hypoproteinemia associated with a bad bed sore. The latter was healed at the time of the patient's death. One other patient died from femoral phlebitis and sagittal sinus thrombosis after he had recovered from a nonspecific urethritis. Six patients had

tidal drainage. Thus, out of 16 patients discharged dead, 5 (31 per cent) had sepsis in spite of the use of tidal drainage. Attention should, however, be called to the fact that in none of these cases did the sepsis involve the genitourinary tract.

Fifteen patients who developed major sepsis and were treated with tidal drainage survived (Table 3). In 3 the sepsis was present at admission, two patients having septic bedsores and the other having pyelitis and a renal stone. Both bedsores were healed, as was the pyelitis, and the kidney stone was removed by the time these patients left my care to resume earning a living. None of this would have been possible without tidal drainage. There were 10 cases of preventable genitourinary-tract sepsis and 2 of preventable bedsores in this group. All were healed at discharge. The genitourinary cases would not now occur and are traceable to inexperience with the apparatus. The other 2 patients represent failures. In one case there was a persistent bacteriuria, and in the other a failure to attain the proper functional end result in the bladder at the time of their discharge.¹ The first patient has been lost sight of. The other was senile at discharge and is now in a public institution. It can be concluded, therefore, that only 13 per cent of patients with nonfatal spinal-cord injuries who develop major sepsis will not have recovered from it at the time of their discharge if they are treated with tidal drainage during their hospital stay. Even this figure is unquestionably too pessimistic in the light of recent experience, and I venture to predict that within

a short time it will be possible to eliminate all major sepsis in such patients

If the above figures are combined and all possible cases included, it is apparent that of the 33 patients who developed major sepsis during their

by this and other means. It therefore seems reasonable to assume that this 13 per cent incidence can be reduced still further in the future, possibly even to the point of elimination of all such sepsis in spinal cord injuries that are properly handled

stay on the ward, in 13 the sepsis was totally unconnected with the use of the tidal drainage apparatus. Nine of these patients died. Twelve other patients had genitourinary sepsis that was preventable. Thus, in only 8 patients out of the 33 that developed sepsis can the tidal drainage be considered a possible causative agent. This is a maximum occurrence rate of 24 per cent.

When the entire group of 101 patients is considered, the efficiency of tidal drainage becomes more apparent. After the elimination of the 12 patients who died within forty eight hours of the receipt of their injury and of the 13 in whom the sepsis was completely unconnected with the use of the tidal drainage, there are 76 patients left, all of whom were treated with tidal drainage and 10 of whom had either genitourinary or bed sore sepsis at discharge. This, as previously stated, is an incidence of 13 per cent. Of these 10, only 6 died—a mortality from such sepsis of 8 per cent. These figures are comparable with the 40 per cent incidence of sepsis among the similar group of patients who were not treated with tidal drainage. As experience has been accumulating, it has been possible to eliminate urethritis, epididymitis and prostatitis, none of these conditions having developed in the last five years. Bedsore, too, have been practically eliminated in the last three years

from the start. The reduction in genitourinary sepsis already accomplished has not only made it possible to eliminate bedsore but has opened up new therapeutic approaches in dealing with the neural deficits of spinal cord injuries. This has led to a great diminution in permanent invalidism and an increase in the earning power on the part of these patients. The intelligent use of tidal drainage is now imperative in every patient who has sustained an injury to the spinal cord. There is no substitute for it.

COMPLICATIONS

I know of no contraindications to the use of tidal drainage. It will not run itself, however, and to work satisfactorily it must be set up properly and be adjusted correctly to the kind of bladder it is serving at the moment. Experience has demonstrated that cystometrograms must be made at least once a week on all patients with spinal cord injuries if they are to receive the utmost benefit from the apparatus. Common conditions that lead to other difficulties are looping of the rubber tubing in such a way as to form traps, air leaks within the apparatus, too short a descending arm of the siphon, failure to take down, clean, sterilize, and reassemble the apparatus once a week, failure to keep the irrigating solution sterile,

allowing the free end of the siphon tube to get below the top of the fluid in the waste bottle, improper instrumentation because of the absence of any complaint of pain on the part of the patient, the use of too large catheters and the presence of an active mass reflex.

Improper instrumentation, the use of too large catheters and the effect of an active mass reflex merit further comment. Instrumentation of an anesthetic urethra and bladder, particularly in the male patient, is, as the figures just quoted show, fraught with grave danger. The possibility of catheterizing a small or strictured urethra or of performing a lithopaxy without causing pain is one that is apt not to occur to the average physician or surgeon. As a result, he fails to realize until after the damage is done that the stylet catheter has not entered the bladder after a slight resistance, as he supposed, but that it has actually perforated the urethra. For the same reason, a fold of bladder wall caught and crushed in a lithorrite causes no pain but results in a perforated bladder and peritonitis.

All my cases of urethritis and epididymitis developed in the patients seen before I had appreciated the futility of and danger in trying to prevent leakage from the bladder by increasing the size of the catheter. A catheter that is too small works better than one that is too large. In the absence of any emptying contraction, leakage is controlled by the pressure of the internal sphincter on the catheter. This is as effective with a small as with a large catheter. Furthermore, the small one has the additional advantage of permitting urethral drainage and thus preventing backing up into and infection of the urethral glands and epididymis. Concerning the type of catheter, my preference is for a rubber rectal tube of proper size in the male and a mushroom-tipped rubber catheter in the female. The location of the hole in the end of the rectal tube instead of the side of the catheter is a great advantage. I have frequently used, however, and many surgeons prefer, either one-way or two-way Foley catheters, but if such a catheter is used in long-standing cases, great care must be taken to see that the expansile bulb that holds it in place is pushed inward and kept from touching the mucous membrane of the bladder. If this is not done, a pressure sore will develop in the bladder wall at the point of contact.

Inasmuch as the reflex bladder can be stimulated to empty itself by pressure or massage through the abdominal wall whenever there is any urine in it, an active mass reflex can and frequently does cause an emptying contraction to develop at highly unexpected and troublesome

moments. In such a reflex, the motor response—set up by a minimal sensory stimulus anywhere on the lower extremities—spreads to involve the muscles of the legs and the abdominal wall. It is this contraction of the abdominal muscles that stimulates the bladder and causes it to empty. Tidal drainage is as yet inefficient in caring for such a condition, and I am not certain how best to deal with this problem. However, some success has been attained by approaching it from the point of view of controlling the reflex rather than draining the bladder, but it has not been possible to reach any final conclusions as yet.

URINE CULTURES

Every one of my patients has had a urine culture once a week during the time he remained on tidal drainage. In addition to a tremendous variety of other organisms, either colon or proteus bacilli have always been grown from these urines so long as the catheter remained in place. Cultures are made by an as yet unpublished method devised by Dr. Daniel W. Badal, a former assistant of mine. This method reduces contaminants to a minimum. In this way it has been learned that, under ordinary circumstances and regardless of whether or not the bladder is normal, the urine of patients with inlying catheters remains sterile for the first seventy-two hours. After that time bacteriuria develops in *every* case. With the proper use of tidal drainage in the abnormal bladder, however, this bacteriuria remains a bacteriuria and does not produce significant cystitis, ureteritis or pyelitis. This has held true even in the cases in which death followed the prolonged use of tidal drainage. Figure 4 shows the normal gross appearance of the genitourinary tract in 2 cases in each of which death occurred after one and a half years of tidal drainage, one of sepsis from a bed sore and the other of acute peritonitis. This is characteristic of all similar cases.

I have used all recommended methods and medicines in an endeavor to sterilize the urines of patients with spinal-cord injuries while on tidal drainage. Mandelic acid, the arsphenamines intravenously and all the sulfonamides, both by mouth and in solution as an irrigating fluid, as well as innumerable other solutions including aqueous iodine, have all failed as long as the indwelling catheter remained in place or as long as a renal or bladder stone was present. With their removal, and provided the patient survived, the urine sterilized itself without medication in every case except one. In that case, the patient was clinically well but still had a bacteriuria at discharge. The end result is not known in this case because follow-up studies could not be made. I have now aban-

done as useless all forms of medication designed to sterilize the urine of patients who are being treated with tidal drainage except for the medicinal effect produced by forcing fluids by mouth at the rate of 5000 cc. every twenty-four hours for

work that is not as yet finished even suggests that with proper training and the use of a rubber urinal the patient may be able to dispense permanently with the indwelling catheter. In the former case, however, he must learn to take down,

FIGURE 4. *Effect of Prolonged Tidal Drainage.*
The gross appearance of kidneys from two patients, each of whom had been treated with tidal drainage for one and a half years.

adults, and by the use of either 1:30,000 potassium permanganate or 0.5 per cent acetic acid as an irrigating solution—preferably the latter. In the absence of residual urine, this bacteriuria is of no clinical significance. With removal of the indwelling catheter, it clears up without further aid.

EXPECTED GENITOURINARY END RESULTS

Patients who have any variety of injury to the spinal cord or cauda equina that is not fatal within the first week now have the right to demand certain genitourinary end results. If there is destruction of the sacral segments or roots, the bladder is useless and it may be necessary to consider eventual transplantation of the ureters to the outside and the permanent use of urinals. If the patient has a transected cord and the mass reflex is not too active, he should expect to be able to lead an active and practically unrestricted wheel-chair life or its equivalent. Moreover, he should certainly expect to be free of the tidal-drainage apparatus except at night. Some recent

clean, sterilize, and set up the apparatus, as well as to fix an indwelling catheter in place in a sterile manner. He will have a bacteriuria, but should not have either clinical cystitis or pyelitis. If the mass reflex is active, tidal drainage will not function sufficiently well to permit such a patient to live outside of an institution at present. All other patients with nonfatal spinal-cord injuries should expect to have a completely normal genitourinary tract with sterile urine at the time of their discharge from institutional care. In addition, the development of bedsores during the patient's recumbency and regardless of the type or level of his cord injury should be cut to the vanishing point by the proper use of tidal drainage and other means, and death from genitourinary sepsis following spinal-cord injury should be eliminated.

SUMMARY

Tidal drainage was not needed in 27 of 165 patients with all types and levels of spinal cord injury.

Tidal drainage was needed but was not used in 37 of these 165 patients. Ten died within forty-eight hours of the receipt of the injury. Twelve out of the remaining 27 had major sepsis at the time of their death or discharge—an incidence of 44 per cent.

Tidal drainage was needed and used in 101 patients. Twelve died within forty-eight hours of the receipt of the injury. Thirty-three of the remaining 89 had major sepsis during their stay on the ward. In 13 the genitourinary sepsis was preventable and in 13 the sepsis had no connection with the use of the tidal drainage. Thus, 76 patients are left, all of whom were treated with tidal drainage, and 10 of whom had either genitourinary or bedsores sepsis at discharge—an incidence of 13 per cent.

A brief description of the newest tidal-drainage apparatus with a built-in cystometer is given.

Certain minimal genitourinary end results applicable to patients with injuries of the spinal cord or cauda equina are listed.

CLINICAL NOTE

A HIP-NAIL DETERMINER

ARCHIBALD R. GARDNER, M.D.,* AND
GARDNER MIDDLEBROOK, A.B.†

LOWELL, MASSACHUSETTS

THE instrument whose description follows allows automatic calculation of the length of the nail, pin or screw that should be inserted into

a simple mathematical slide rule transformed for the purpose of giving, by two measurements on the x-ray film and one movement of the slide, a direct calculation of the proper length of nail, pin or screw to be used. The particular instrument that we have been successfully using for over two years is shown in Figure 1. The directions for its use are as follows:

- (1) Set 0 on the B scale opposite 9.0 on the A scale (9.0 cm. is the actual length of the direction-finder).
- (2) Place the determiner against the x-ray film (Fig.

FIGURE 1.

the head of the femur to accomplish internal fixation of a fracture of the femoral neck. There are now in use many known techniques by which this internal fixation is performed, and, because in the one¹ which we chose to use a direction-finder is employed, we explored the possibility of applying

2), and read off the number on the B scale corresponding to the length of the direction-finder from the left-hand end of the determiner.

(3) Place the determiner against the x-ray film and measure the distance from the proximal end of the direction-finder to the end of the femoral head on the A scale.

(4) Move the slide so that the B-scale number determined in (2) is opposite the A-scale number determined in (3).

*Honorary surgeon, Lowell General Hospital; consulting surgeon, St. Joseph's Hospital, Lowell, and State Hospital, Tewksbury, Massachusetts.
†Student, Harvard Medical School.

(5) The point where the left hand end of the slide falls on the C scale determines the length of nail to be used.

The distance between the proximal end of the nail and the tip of the femoral head, which we have preferred to make 1.5 cm., may be as widely varied as desired in the construction of the de-

FIGURE 2. X-Ray Film with the Engel-May Direction Finder in Place.

terminer, depending on how much impaction one expects or prefers and on how nearly the head of the nail, pin or screw is made flush with the surface of the femur below the greater trochanter. Furthermore, although the length of the Engel-May direction-finder happens to be 9.0 cm., it should be pointed out that, according to the length of the particular direction-finder or radio-opaque stenciled metal plate² that one prefers to employ, a scale can be empirically devised to give the proper calculated results. The instrument can be readily fashioned as follows:

An ordinary wooden slide rule (price, 50 cents to \$1.00) is sanded well to receive the numbers. An A scale is

constructed in centimeters up to 14 or 15 cm.,—in pencil for all preliminary work and in India ink for the final product (the first nine centimeters—the length of the Engel-May finder—are not marked, since there is always some magnification of the finder on the x-ray film). On the slide next to the A scale a distance of 1.5 cm. (the preferred distance from the tip of the pin to the tip of the femoral head when the head of the pin is flush with the bone) is measured from its tip, and starting there, a B scale is made in centimeters. After the A and B scales have been constructed, a C scale is made by setting 1.3 on the B scale opposite certain numbers on the A scale, as follows:

9.8 equals	7.5 - C
10.4 equals	8.0 - C
11.0 equals	8.5 - C
11.6 equals	9.0 - C
12.2 equals	9.5 - C
12.8 equals	10.0 - C
13.4 equals	10.5 - C

These points should be marked and labeled, and the intervening points interpolated. Obviously, the C scale is not a centimeter scale. For convenience in the operating room the five directions given above are printed on the reverse side of the slide rule, and the whole instrument is varnished, care being taken not to affect the slide.

In order to test the accuracy of this device one has only to set up practical problems, remembering that few femoral necks in practice are shorter than 8.8 or longer than 12.0 cm., and that fortunately, in most cases, the shorter the hip, the smaller the x-ray magnification, and the longer the hip, the greater the magnification. The margin of error in the practical application of this instrument, provided it is properly used, is well within the range of safety.

MEDICAL PROGRESS

PERIPHERAL VASCULAR DISEASE*

ROBERT W. WILKINS, M.D.,† AND CARL K. FRIEDLAND, M.D.‡

BOSTON

PERIPHERAL vascular disease is assuming greater importance in medicine, not only because it is becoming commoner in the ageing population,¹ but also because it is being more frequently recognized as a sign of possible remote or widespread disease. Recent articles have emphasized the fact that not only arteriosclerosis but also thromboangiitis obliterans, Raynaud's disease and scleroderma may be accompanied by vascular disturbances in the lungs,²⁻⁴ heart^{2, 5} or brain.^{2, 6, 7} Furthermore, it has been pointed out that systemic diseases such as periarteritis nodosa,⁸ Boeck's sarcoid,^{9, 10} lupus erythematosus and dermatomyositis¹¹ may manifest themselves by vascular signs and symptoms in the extremities. However, in spite of an enlarging interest in the subject, progress in the understanding of the fundamental nature of the various peripheral vascular diseases has been slow. For this reason preventive and therapeutic measures have been largely nonspecific and symptomatic. The first part of this review will attempt to summarize the current concepts of the etiology and pathology of diseases of the peripheral arteries, the second to analyze some recent suggestions for their symptomatic treatment, the third to give a brief résumé of peripheral vascular diseases resulting from exposure to cold, and the last to present the newer aspects of diseases of the veins, especially as they concern the practitioner of internal medicine.

DISEASES OF THE PERIPHERAL ARTERIES

Atherosclerosis, by all odds, is the most prevalent and economically the most important vascular disease of adults. Recent studies¹² indicate that this disease is the result of a selective invasion of the arterial intima by, and the localization therein of, cholesterol-laden (foam) cells derived from the reticuloendothelial system. Following the breakdown of these cells, de-esterified cholesterol is deposited in the subintima as plaques, which act as foreign bodies. Vascularization, fibrosis and

calcification of such plaques occur in varying degrees to produce the familiar lesions of atherosclerosis. Atheromatous plaques may slowly enlarge to compromise the lumens of the vessels and cause gradual occlusion, or may suddenly undergo subendothelial hemorrhage and cause rapid occlusion.¹³

Hereditary predisposition to atherosclerosis and to the diseases with which it is commonly associated must be of great significance in determining its occurrence. Also, the fact that various hypercholesteremic disorders, such as diabetes mellitus,^{14, 15} hypothyroidism,¹⁶ nephrosis¹⁷ and various xanthomas,¹⁸ are so frequently complicated by atherosclerosis indicates that a derangement of lipid metabolism plays a fundamental part in its etiology. Likewise, the greater frequency of atherosclerosis in arteries under increased intravascular tension, whether due merely to hydrostatic effects (in the lower half of the body¹⁹) or to systemic (essential²⁰) or pulmonary (mitral stenotic²¹ or emphysematous²²) hypertension, suggests the importance of high arterial pressure in the causation of the disease. The etiologic roles of compression and collapse of the vasa vasorum, and of depressed oxygen dissociation properties of the blood,²³ although of great interest, are less clear.

Thromboangiitis obliterans etiologically remains a mystery. Its pathology suggests that it is an infection involving the veins and arteries in a proliferative inflammatory reaction beginning in the intima, extending to the entire vessel wall and leading to occlusive thrombosis with subsequent fibrous organization.²⁴ Streptococci,²⁵ trichophytons^{26, 27} and *Rickettsia prowazekii*²⁸ all have been suggested as possible etiologic agents. Its predilection for males, young adults, Jews and tobacco-smokers is generally recognized but unexplained. Thrombophlebitis migrans is a frequent precursor or concomitant, but produces little local or systemic reaction, although pulmonary embolism from this source has been known to occur.²⁹

The course of thromboangiitis obliterans is extremely variable,²⁴ and its distribution patchy; it may be slowly or rapidly progressive depending on whether it involves small segments of a single vessel or large segments of a number of vessels. At

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas Company, 1942 \$5.00).

present there is no indication that any single preventive or therapeutic measure is specific. Equally good therapeutic results are achieved by the simplest hygienic measures and the least meddlesome procedures.³⁰

Raynaud's disease classically appears in asthenic young women in whom attacks of acral vasospasm occur in response to chilling and to emotional stimuli. Accordingly, its manifestations are thought to be due to an abnormal vasoconstrictor response to local cold^{31, 32} or to a hyper-reactivity of the sympathetic nervous system.³³ However, its frequent association with scleroderma,³⁴ calcification of subcutaneous tissues,^{4, 35} decalcification of bone,⁴ pulmonary fibrosis^{3, 4} and widespread vascular disease^{8, 11} suggests that Raynaud's phenomenon, in many cases, is merely a local manifestation of a more serious systemic disorder.

Periarteritis (polyarteritis) nodosa continues to be reported in the literature with ever-increasing frequency.³⁶ Peripheral vascular involvement, when present, may be characterized by palpable nodules along the course of superficial arteries, pulsating subcutaneous nodules (aneurysms), obliteration of the pulse in small arteries and Raynaud's phenomenon.⁸ Its pathology is essentially a fibrinoid necrosis of the arterial wall with an associated acute, subacute or healing inflammatory cellular reaction that also involves the perivascular tissues.

It has been pointed out that the frequent association of periarteritis with asthma, urticaria and eosinophilia suggests a hypersensitive background in its causation.³⁷⁻³⁹ Lesions typical of periarteritis are said to have appeared in patients who had hyper-reactions after the administration of foreign serum, sulfonamide therapy or both.^{37, 38} They have also been reproduced in the laboratory rabbit by injecting a single large dose of horse serum.³⁹ These observations arouse speculation whether the increasing incidence of periarteritis may be due to the increasing use of serums, vaccines and sulfonamide drugs.

SYMPTOMATIC TREATMENT OF OCCLUSIVE ARTERIAL DISEASE

The ischemia caused by arterial occlusion is probably the most potent stimulus for the promotion of collateral circulation,⁴⁰ which, in turn, is certainly the most important factor in determining the ultimate effects of an arterial occlusion.⁴¹ These facts are still little appreciated, if one is to judge from the great variety of therapeutic measures reported to be of more or less specific value in the treatment of occlusive arterial disease.

Intermittent venous occlusion is claimed to be beneficial,⁴² not only because it may be followed (after release) by reactive hyperemia,⁴³ but also because it has been reported to produce an increase in arterial blood flow during the period of obstruction.⁴⁴ It has recently been shown, both in man⁴⁵ and in animals,^{46, 47} that venous obstruction decreases arterial blood flow during the period when venous pressure is increased (above about 30 mm. of mercury). It is true that following the release of venous obstruction there is a short period of reactive hyperemia in normal limbs, but compared with that following the release of arterial occlusion it is small in amount,⁴³ and probably does not repay the blood-flow debt incurred during the venous obstruction.⁴⁸ Furthermore, following prolonged periods of continuous^{43, 46} or intermittent^{45, 48} venous obstruction there is no lasting increase in resting blood flow.

In limbs with severe arterial impairment, the mechanism of reactive hyperemia is apparently being constantly invoked. This has been shown by the fact that after the circulation in such limbs has been completely occluded for periods up to fifteen minutes, there is no increase in blood flow (on release of the circulation) over the previous resting level.⁴⁹ This is in sharp contrast to the marked reactive hyperemia that occurs in normal limbs following the release of arterial occlusion.⁵⁰ It indicates that these diseased limbs have constantly as great a blood flow as is possible in response to the stimulus of blood-flow deprivation. It shows the futility of attempting to increase arterial blood flow in such limbs by reactive hyperemia, especially with such an ineffective method as venous occlusion. There is a possibility that distending the capillary bed may be beneficial in these cases, either directly, or indirectly, by favorably affecting lymph flow, but this has not yet been proved.

Recent studies indicate that positive external pressure greatly decreases blood flow, whereas negative external pressure does not significantly increase it in the limbs.⁵¹ For these reasons, it seems doubtful that *alternate suction-pressure techniques* are of benefit in improving blood flow.

Producing reflex vasodilatation by warming the body increases the blood flow in the forearm and calf as well as in the hands and feet.⁵² Provided diseased arteries are capable of further dilatation, warming the body should be helpful temporarily in improving the nourishment of the tissues. However, local heat, unless properly controlled, may increase the metabolic demands of the tissues out of proportion to the available blood supply,⁵³ and thereby do more harm than good. The danger

of burning limbs in which the circulation is minimal also needs constant emphasis.

The role of the sympathetic nervous system is much more important in determining the blood flow in the skin areas of the extremities than in the muscular areas.^{52, 54, 55} However, it appears that, in the forearm and calf, sympathetic nervous activity can alter the blood flow as much as 200 to 300 per cent.⁵² Apparently in these parts active vasodilatation, as well as vasoconstriction, is mediated over the sympathetic nervous system. These physiologic considerations should be borne in mind when surgical sympathectomy is contemplated for the relief of peripheral arterial disease.

Surgical sympathectomy is most clearly indicated when it can be shown that reflex sympathetic vasoconstriction plays an important role in causing ischemia.^{41, 56} This may be demonstrated by producing reflex vasodilatation (warming the body) or by functional sympathetic block (producing spinal anesthesia, or procainizing the sympathetic ganglions or peripheral nerves). If there is a definite improvement in blood flow after such a procedure, it is reasonable to expect a similar result after surgical sympathectomy. It has been suggested that sympathectomy may also promote the development of collateral circulation.⁵⁷

Following preganglionic sympathectomy the skin of extremities with arterial disease often improves, both in color and temperature. However, it has been questioned whether this necessarily indicates improvement in general nutrition in the limb.⁵⁸ Furthermore, as yet no convincing studies have appeared demonstrating that blood flow is improved in sympathectomized muscular areas as compared with unsympathectomized control areas (in the opposite limb when there is comparable arterial disease). Symptomatic improvement, and increased claudication times following surgical operation and bed rest, although suggestive,^{56, 57, 59} are not conclusive evidence of an improvement in circulation due to the operation.

The natural reparative processes of the body make it necessary to control rigidly the experimental trial of any therapeutic procedure for peripheral vascular disease. This is especially true when such a specific procedure is applied along with various nonspecific measures, such as bed rest, warmth and general hygiene. Finally, when the procedure in question operates generally in the body, making it impossible to compare its effects in one part with the status in a control part, the physician can have recourse only to the statistical method in a large series of patients alternately treated with the procedure. Until studies of this kind are done there will continue to be

disagreement as to the value of various *hormones, tissue extracts* and *intravenous solutions*.

PERIPHERAL VASCULAR DISEASES DUE TO EXPOSURE TO COLD

Submarine warfare has focused attention on *immersion foot*—a vascular disease of the extremities due to exposure. This condition, seen in survivors from ships torpedoed in the cold waters of the North Atlantic, is in no way different in its etiology and pathology from the trench foot observed in the last war.⁶⁰ In either case, the lesion is caused by temperatures sufficient to chill but not to freeze the tissues. Experimentally, exposing an extremity to cold causes formation of edema fluid with a relatively high protein concentration.⁶¹ This is interpreted as meaning that cold insufficient to freeze the tissues can produce an increase in capillary permeability and an inflammatory exudate. The edema formation is roughly proportional to the degree of cold and to the duration of exposure. Also, experimentally cooling the peripheral nerves may abolish sensory, motor, vasomotor and sudomotor functions.⁶²

Shipwrecked sailors exposed to cold for prolonged periods develop swollen, discolored, anesthetic and even pulseless extremities, the distal portions usually being affected most severely.^{60, 63-66} Dependency and immobility of the limbs add to the swelling, and possibly to the severity of the vascular lesions. Constricting footgear, under these conditions, also seems to increase the resultant damage. Men habitually exposed to warm environments, such as those of the Mediterranean and African races, and those employed in boiler rooms, apparently are more susceptible than others to immersion foot, but there is no evidence that this susceptibility is due to a pre-existing vascular abnormality.⁶⁰ However, one episode of immersion foot apparently renders the feet less resistant to further exposure to cold.⁶⁷

In the severest cases reported to date, the feet and lower legs have been swollen and anesthetic almost to the knees, and the distal halves of the feet have appeared gangrenous. A low-grade fever is not uncommon for the first few days after rescue and is no cause for alarm. A high temperature, usually indicative of infection, is more serious.

After rescue and warming of the body the limbs become hyperemic and remain so for several days to six weeks. The hyperemia is associated with an increase in edema formation and occasionally with the appearance of blebs containing serous or serosanguineous fluid. In cases in which the hyperemia is most intense, sweating and sensation are usually absent, and subcutaneous hem-

orrhages may occur. When the hyperemia fades, the skin of the feet desquamates. Gangrene, if present, is rarely more than superficial, but infection, either in the presence or absence of gangrene, constitutes a serious complication.

The anesthesia disappears quickly in the proximal areas but only slowly in the distal areas, where nerve damage is more severe. A burning, tingling pain accompanies the return of sensation and often persists until nerve regeneration is complete. Sweating and sensation reappear in the same areas practically simultaneously.

Treatment should be directed toward avoidance of further injury, reduction of the hyperemia and edema, and maintenance of strict asepsis. The patient should be lifted aboard the rescuing vessel and body warmth restored, but the limbs should be kept cool and elevated until the hyperemia subsides. Application of cold packs is the most effective means of cooling, but spraying water into the air current of a fan directed toward the feet or simply exposing the limbs to a room temperature of 70°F. may suffice. Moderate cooling reduces hyperemia, promotes resorption of edema fluid and blebs, prevents hemorrhage into the tissues and minimizes pain. If pain is not diminished or abolished by cooling, opiates are employed, and even nerve crush may be considered.⁶⁵

Sympathectomy is not advisable in the hyperemic stage because blood flow in the large vessels is already maximal. However, if after recovery there is evidence of organic or functional (vasoconstrictor) arterial disease, sympathectomy may be indicated.⁶⁷

Survivors of ships torpedoed in subtropical or tropical waters also develop swollen, painful feet, but do not present the cutaneous vascular changes seen in immersion foot.⁶⁸ These men, subjected to intense heat and short water rations, become dehydrated and develop nutritional deficiency due to an inability to swallow the concentrated emergency rations. Cheilitis, glossitis and stomatitis, in addition to peripheral neuritis, suggest that vitamin B deficiency is an important factor. Thus protein and vitamin deficiencies probably contribute to the edema and the pain.

Chilblain and *pernio* (erythrocyanosis) deserve mention because of their relation to immersion foot.⁶⁷ Although also due to exposure to cold, they are seen, in contrast to immersion foot, most commonly in patients with a history of cool limbs in summer as well as winter. This suggests that they are liable to occur on the basis of a pre-existing circulatory disturbance in the limbs.

*Chilblain*⁶⁷ occurs on the dorsum of the fingers, hands or feet as a localized, warm, red, pruritic swelling that may disappear in a few days, but

more often becomes an indolent lesion, dull red or violaceous, proceeding to painful bleb formation or ulceration. It is due to repeated or prolonged exposure to cold insufficient to freeze the tissues and appears (in temperate zones) at the onset of cold weather, recurring each year in the same exposed areas of the body.

Pernio,^{67 69} an essentially similar lesion involving the lower parts of the legs, occurs especially in women because their mode of dress affords inadequate protection for their legs against cool weather.

Strictly speaking, *frostbite*, in contradistinction to immersion foot, chilblain and pernio, is due to freezing of the tissues, with mechanical disruption of cell structure.⁷⁰ Actually, however, it frequently occurs in association with one of the other syndromes. When the freezing is superficial, thawing is followed by the typical cutaneous response to injury, namely local reddening, wheal and flare, but, when the skin is frozen more extensively, or when the subcutaneous tissues are involved, it is accompanied by bleb formation, or by necrosis and ulceration. Thawing should be slow, not only to lessen the pain and edema formation, but also to reduce the secondary tissue damage that occurs during the excessive local reaction when thawing is too rapid. Thus the time honored remedy of applying cold (slight relative warmth) to a frozen area has a rational basis. Rubbing or friction, on the other hand, is not recommended, since it but further traumatizes already damaged tissues.

DISEASES OF THE PERIPHERAL VEINS

Varicose veins, still numerically the most important problem of the peripheral venous system, are best treated by surgical ligation, excision or injection.⁷¹ Unless, however, the possible variations in the superficial venous drainage of the limbs are taken into account at the time of operation, varicosities are liable to recur.^{71 72} Furthermore, following therapeutic injection of the superficial veins, chemical thrombosis may extend into the communicating and deep veins and cause post-treatment edema and pain. This complication has been treated by the use of the anticoagulant heparin.⁷³

Varicose veins, when extensive, may be responsible for cardiovascular symptoms such as fatigue, exertional dyspnea, dizziness, precordial distress and syncope in the orthostatic position.⁷¹ In this position the return of blood through superficial, as contrasted with deep, veins in the legs is relatively slight, and is but little affected by muscular activity, even in normal persons.⁷³ When there are varicose veins with incompetent or even throm-

bosed^{76, 77} valves, actual stagnation of blood occurs in the varices, which may pool a sizable portion of the total blood volume. This results in an insufficient return of venous blood to the heart and causes symptoms of orthostatic collapse. Some patients have been greatly relieved of these symptoms following proper treatment of their varicose veins.⁷⁴

Phlebothrombosis is an insidious disorder, since it is accompanied by little or no local inflammatory reaction to signal its presence or to fix the thrombus in situ.⁷⁷ Consequently, its first sign may be the occurrence of embolism in the lungs.⁷⁸⁻⁸⁰ Conditions predisposing to venous thrombosis, such as myocardial failure, malignancy, obesity, debility, severe infections, varicosities, trauma and surgery, probably operate in a variety of ways.^{77, 80, 81} One of these certainly is to slow markedly the circulation in the limbs.^{82, 83} Postoperatively, maximal slowing of the circulation in the legs is said to coincide with the time when phlebothrombosis and pulmonary embolism most commonly develop.⁸³ Other factors recently suggested as possibly important in predisposing to phlebothrombosis include the occurrence of hyperprothrombinemia after surgical operations⁸⁴ and the development of cold agglutinins after certain infections.⁸⁵

Deep breathing, bicycle exercises, and flexion and extension of the extremities are useful in speeding the circulation and lessening the danger of venous thrombosis.^{82, 86} Some authors⁸⁷ have recommended the administration of thyroid for this purpose. Unfortunately in debilitated and especially in cardiac patients, these procedures are difficult to carry out. However, measurement of the circumference of the limbs and the application of Homans's maneuver—dorsiflexion of the foot to elicit pain in the calf or popliteal space or both—can and should be done daily in order to detect the presence of phlebothrombosis.⁷⁹ Determinations of venous pressure, especially after exercise of the limb, may indicate the presence of local venous obstruction.⁸⁸ Venography has also been recommended to show the location and extent of the lesions,⁸⁹ but even if venogram is negative, thrombosis is not without danger of serious or that rigid precaution use of contrast media diagnosis of diseases of the treatment of sed by the desire on. This latter importance of separation

has formed, must take precedence over therapeutic procedures against phlebothrombosis per se. Therefore, active or passive motion is contraindicated when it seems probable that thrombosis has occurred.⁷⁷ Moreover, rest, immobility, local heat and elevation of the limbs may be inadequate in preventing embolization.⁹¹ For these reasons a more positive approach, venous ligation, is recommended. It has been emphasized that unilateral ligation may not be sufficient, since the predisposing factors to phlebothrombosis operate generally, and quite often thrombosis is present in both legs.⁷⁹ Furthermore, embolization is more liable to occur from the less obviously involved (less symptomatic) limb. Finally, ligation should be performed high enough to preclude the possibility of embolization from proximal extension of the clot. In some cases it may be necessary to ligate even as high as the inferior vena cava.⁹²

Thrombophlebitis is less frequently a source of pulmonary embolism than is phlebothrombosis because the associated inflammatory reaction organizes the clot and prevents its breaking off. However, if the thrombus extends proximally, the fresh clot may not be sufficiently adherent, and emboli may be broken off by the current of blood.⁹³ Therefore the same therapeutic measures as those used in phlebothrombosis should be considered. In addition, if the extremity is cold, painful, sweaty, pale or cyanotic, procaine block of the sympathetic ganglions is recommended for relief of arterial spasm.⁹⁴ Rarely is the associated spasm severe enough to cause gangrene.⁹⁵ Moreover, not all patients with thrombophlebitis have abnormal arterial constriction in the affected limb; some may have a warm limb with good color.⁹⁶

Lately there has been considerable interest in the use of anticoagulant agents for the prevention and treatment of intravascular thrombosis, but unless carefully controlled these agents may lead to severe hemorrhages.⁹⁷⁻¹⁰⁰ In spite of its high cost, heparin is probably still the anticoagulant of choice.¹⁰¹ Administered intravenously its action is immediate and may be controlled by varying or stopping its administration, by giving protamine or by transfusions of plasma or blood. Dicoumarin, on the other hand, although inexpensive and easily (orally) administered, has several disadvantages. Its action is delayed and unpredictable, and since it has no effective antidote, its control may be difficult.¹⁰¹

* * *

Considered in their wider aspects, diseases of the peripheral vessels should be of interest not only to surgeon specializing in them, but also to the physician of general or internal medicine. This

is so because these affections may be the first or only sign of existing or impending damage in more vital organs that are supposed to be the primary concern of the internist.

bosed^{76, 77} valves, actual stagnation of blood occurs in the varices, which may pool a sizable portion of the total blood volume. This results in an insufficient return of venous blood to the heart and causes symptoms of orthostatic collapse. Some patients have been greatly relieved of these symptoms following proper treatment of their varicose veins.⁷⁴

Phlebothrombosis is an insidious disorder, since it is accompanied by little or no local inflammatory reaction to signal its presence or to fix the thrombus in situ.⁷⁷ Consequently, its first sign may be the occurrence of embolism in the lungs.^{78, 80} Conditions predisposing to venous thrombosis, such as myocardial failure, malignancy, obesity, debility, severe infections, varicosities, trauma and surgery, probably operate in a variety of ways.^{77, 80, 81} One of these certainly is to slow markedly the circulation in the limbs.^{82, 83} Postoperatively, maximal slowing of the circulation in the legs is said to coincide with the time when phlebothrombosis and pulmonary embolism most commonly develop.⁸³ Other factors recently suggested as possibly important in predisposing to phlebothrombosis include the occurrence of hyperprothrombinemia after surgical operations⁸⁴ and the development of cold agglutinins after certain infections.⁸⁵

Deep breathing, bicycle exercises, and flexion and extension of the extremities are useful in speeding the circulation and lessening the danger of venous thrombosis.^{82, 86} Some authors⁸⁷ have recommended the administration of thyroid for this purpose. Unfortunately in debilitated and especially in cardiac patients, these procedures are difficult to carry out. However, measurement of the circumference of the limbs and the application of Homan's maneuver — dorsiflexion of the foot to elicit pain in the calf or popliteal space or both — can and should be done daily in order to detect the presence of phlebothrombosis.⁷⁰ Determinations of venous pressure, especially after exercise of the limb, may indicate the presence of local venous obstruction.⁸⁸ Venography has also been recommended to show the location and extent of the lesions,⁸⁹ but even though the venogram is negative, thrombosis is not excluded.⁷⁹ It is also well to remember that angiography is not without danger of serious or even fatal toxic reactions, and that rigid precautions should be observed in the use of contrast media in the roentgenographic diagnosis of diseases of the peripheral vessels.⁹⁰

The treatment of phlebothrombosis has been confused by the desire to avoid the danger of embolization. This latter consideration is of so much greater importance that measures designed to prevent the separation of the thrombus, once it

has formed, must take precedence over therapeutic procedures against phlebothrombosis per se. Therefore, active or passive motion is contraindicated when it seems probable that thrombosis has occurred.⁷⁷ Moreover, rest, immobility, local heat and elevation of the limbs may be inadequate in preventing embolization.⁹¹ For these reasons a more positive approach, venous ligation, is recommended. It has been emphasized that unilateral ligation may not be sufficient, since the predisposing factors to phlebothrombosis operate generally, and quite often thrombosis is present in both legs.⁷⁹ Furthermore, embolization is more liable to occur from the less obviously involved (less symptomatic) limb. Finally, ligation should be performed high enough to preclude the possibility of embolization from proximal extension of the clot. In some cases it may be necessary to ligate even as high as the inferior vena cava.⁹²

Thrombophlebitis is less frequently a source of pulmonary embolism than is phlebothrombosis because the associated inflammatory reaction organizes the clot and prevents its breaking off. However, if the thrombus extends proximally, the fresh clot may not be sufficiently adherent, and emboli may be broken off by the current of blood.⁹³ Therefore the same therapeutic measures as those used in phlebothrombosis should be considered. In addition, if the extremity is cold, painful, sweaty, pale or cyanotic, procaine block of the sympathetic ganglions is recommended for relief of arterial spasm.⁹⁴ Rarely is the associated spasm severe enough to cause gangrene.⁹⁵ Moreover, not all patients with thrombophlebitis have abnormal arterial constriction in the affected limb; some may have a warm limb with good color.⁹⁶

Lately there has been considerable interest in the use of anticoagulant agents for the prevention and treatment of intravascular thrombosis, but unless carefully controlled these agents may lead to severe hemorrhages.⁹⁷⁻¹⁰⁰ In spite of its high cost, heparin is probably still the anticoagulant of choice.¹⁰¹ Administered intravenously its action is immediate and may be controlled by varying or stopping its administration, by giving protamine or by transfusions of plasma or blood. Dicoumarin, on the other hand, although inexpensive and easily (orally) administered, has several disadvantages. Its action is delayed and unpredictable, and since it has no effective antidote, its control may be difficult.¹⁰¹

CASE 29261

PRESENTATION OF CASE

A sixty-year-old Cuban was referred to this hospital because of a persistent cough and a mediastinal tumor.

For years the patient had been bothered by a slight nonproductive cough. Three months before entry the cough became worse, particularly when the patient was lying down, and became productive of one to two teaspoonfuls of gray-white phlegm. At that time he developed "a tired feeling" in the upper sternum. A month later he had intermittent dull, burning pains beneath the sternum and in the upper left chest, which were unrelated to effort or position and seemed to radiate through to the left scapula. The pains gradually increased in frequency and became almost constant. Exertional dyspnea, unassociated with orthopnea, developed and gradually became worse. One month before entry the patient's voice became hoarse, but there was no dysphagia. There was no palpitation, ankle edema, cyanosis, bloody sputum or weight loss.

The family history was noncontributory. The patient's wife had never been pregnant. The patient denied a penile sore, gonorrhea or a skin rash. Seven years before admission he developed filariasis, characterized by fever, "large glands" in the groin and "white urine" from the left kidney. A biopsy of a groin node showed filaria. He was treated with "ice therapy," and the illness promptly cleared. Since that time the patient had found it necessary to travel in the New England states or Canada during the summer months to avoid relapses.

Physical examination disclosed a pale, sallow, somewhat dehydrated man who coughed frequently, producing frothy yellow sputum. The pupils were equal and reacted to light and accommodation. The neck veins were not distended. One examiner felt a tracheal tug. The cardiac apical impulse was felt 8 cm. to the left of the mid-sternal line in the fourth interspace. The sounds

were of good quality, and no murmurs were heard. The second aortic sound was louder than the pulmonic; neither was accentuated. The lungs were clear; the abdomen was negative.

The blood pressure was 100 systolic, 60 diastolic, in both arms. The temperature, pulse and respirations were normal.

The hemoglobin was 12.8 gm., and the white-cell count 12,800, with 74 per cent neutrophils, 14 per cent lymphocytes and 12 per cent monocytes. The urine was normal. Blood Hinton and Wassermann tests done in dilution were repeatedly negative. The sputum did not contain acid-fast organisms on one examination. The nonprotein nitrogen was 24 mg. per 100 cc., and the protein 71 gm. An electrocardiogram showed slight sinus arrhythmia, with an average rate of 80. The PR interval was 0.15 second. T₁ was low, and T₂ and T₃ upright; T₁ showed a slight late inversion. The QRS complex was slightly blurred.

A chest roentgenogram (Fig. 1) disclosed a rounded mass with fairly sharply defined borders in the region of the aortic knob and descending portion of the aortic arch. This mass was about 80 cm. in diameter and could not be separated from the shadow of the aorta. Pulsations were visible over it, but their amplitude was less than that of the heart beat. The heart was not increased in size or abnormal in shape. The visible portion of the aorta was not abnormal. The left bronchus was displaced downward and inward by the mass and was also somewhat narrowed, but not blocked. There was an area of dullness in the right upper lobe immediately lateral to the mass described. The character of the dull area suggested a localized atelectasis. The diaphragm was low on both sides, and its respiratory movements were limited. There was no evidence of air trapping. An angiogram, although correctly timed was unsatisfactory; the film taken at the time the opaque substance (Diodrast) passed through the aorta was blurred because of motion.

An operation was performed on the sixteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM B. BRIDG. This man had been quite well up to three months previous to admission, when he began to cough and show signs of bronchial irritation on the left. Certainly his symptoms did not indicate that he had heart disease, and examination of the heart confirmed this. The electrocardiogram was not conclusive concerning any particular cardiac disease.

A whole paragraph discusses filariasis, but I shall devote little time to this diagnosis, since I know practically nothing about it.

*On leave of absence

DR. TRACY B. MALLORY: Dr. Cordero, who is here, can perhaps tell us about it.

DR. BREED: I hope to hear from him. I do not believe, however, that filariasis produces anything of this nature in the upper mediastinum. At the moment, unless I hear something from someone who knows more about it than I do, I shall discard the whole question of filariasis.

It is interesting that one person felt a tracheal

says about the films. There is one thing that I wondered about, Why was he not bronchoscoped? The x-ray film showed a narrowing of the left bronchus but the patient was operated on before bronchoscopy was performed.

DR. GEORGE W. HOLMES: He had been bronchoscoped in Cuba.

DR. BREED: Did you have a report of the bronchoscopy in Cuba?

FIGURE 1. Roentgenogram of Chest.

The larger arrow points to the collapsed left upper lobe, and the smaller one to the residual lipiodol.

tug. I shall certainly not accept that if only one person felt it. It is a sign difficult to be sure of, and unless everybody felt it, it should not be accepted.

The blood showed a moderate degree of anemia but nothing characteristic. They did their best to obtain a positive Hinton test, having done many tests in dilution, but it was repeatedly negative.

We then come to the x-ray studies. The diagnosis depends almost entirely on what Dr. Holmes

DR. HOLMES: It was essentially negative.

DR. BREED: They found no narrowing of the left bronchus by bronchoscopy?

DR. HOLMES: No.

DR. BREED: The problem narrows down to whether he had a cystic or a solid tumor of the mediastinum or an aneurysm. I should like to ask one question before Dr. Holmes talks. Could an aneurysm of the aorta displace the left bronchus downward and inward?

DR. HOLMES: I think it could.

DR. BREED: I do not quite understand how, anatomically, an aneurysm of the aorta could displace the left bronchus downward and inward.

DR. RALPH ADAMS: The left primary bronchus comes out anterior to the aortic arch as it completes its turn posteriorly, so that mechanically it would be possible for an aneurysm of the antero-lateral surface of the arch of the aorta, just before it straightens out, to push the bronchus downward and inward.

DR. BREED: It may be mechanically possible, but I do not believe that I have ever seen an aneurysm of the aorta that displaced the bronchus in this fashion.

We have to consider a cystic or solid tumor arising somewhere in the mediastinum or from a bronchus. This man had some atelectasis of the left upper lobe. He may have had a carcinoma of the bronchus with a large metastatic lymph node. From the progress of the story, I am inclined to think that it was probably a malignant rather than a benign process. I should also like to ask if there was any accurate preoperative diagnosis put forward. I suspect they operated for diagnosis as well as treatment.

DR. HOLMES: This patient was carefully studied in Cuba by an excellent man, Dr. Pedro Finares, and I have some of his films here, as well as some of our own. He was referred to this hospital largely for treatment. They felt reasonably certain of the diagnosis. When we started to study the patient here we were unable to make a definite diagnosis. We eventually arrived at the same place that Dr. Breed has, namely, that this was either a tumor or aneurysm. Between what was done in Cuba and here, he had every possible test performed and we were still somewhat in doubt about the diagnosis.

DR. BREED: I still think that, if he had been bronchoscoped here, something might have been found.

DR. HOLMES: I do not believe so, and I shall tell you why in a moment.

This film was taken by Dr. Finares, after the injection of lipiodol. You can see the outline of the trachea at its bifurcation, this is the right descending bronchus, and here is the left descending bronchus. The mass lies in the angle between the bronchus and the trachea and has compressed the bronchus. If you look at the earlier films you notice an area of atelectasis in all the films. If the patient had a plugged bronchus it would be the bronchus leading to this area, and the bronchoscope would not reach that bronchus. Bronchoscopic examination, therefore, would be of no particular value.

This is the mass here. You can see it in the

lateral view, and we were never able to separate it from the aorta. This film was taken also by Dr. Finares and is a kymogram, a graphic method of showing whether or not pulsation is present. You do not have to rely on fluoroscopy. These lines represent the excursion of the heart or organ you are studying during the test. Over this area there is some excursion, not as marked as it is in the heart. We also have films over a considerable period of time, and there is a progressive increase in size, not by starts and stops. A portion of the lung is collapsed, and of course that is more likely to occur with a tumor that arises in and plugs a bronchus than with an aneurysm. An aneurysm can produce a collapsed lung, but it is only fair to say that an aneurysm of this size and position is unlikely to do so.

Then we tried taking over-exposed films to see if we could determine whether there was calcium in the walls of the tumor. The man had a negative Hinton test. So if it was an aneurysm it must have been on some basis other than syphilis. We were unable to demonstrate calcium. The heart was not enlarged. Not all cases of aneurysm have an enlarged heart, but a good many of them do, so that ought to help some.

Then we attempted to do a stunt that we thought would give us the answer—an arteriograph. The patient was willing to submit to it and the dye was injected into a vein. As you see, it first went to the right side of the heart; later it was in the pulmonary circulation; then a little later you see it in the left side of the heart. At that time it should have been in the great vessels and have given us the answer, but I was unable to interpret the findings. The film was not quite good enough, and the density of the dye was not great enough, possibly owing to the fact that it was injected too slowly. I think it is fair to say that the shadow of the tumor did not change appreciably in density, which it should have done if it were an aneurysm.

DR. BREED: This shadow looks almost continuous from the top of the heart.

DR. HOLMES: No; I do not believe that it is. We were not able to make a positive diagnosis, but we thought that this evidence was against aneurysm.

DR. BREED: Have you ever seen by x-ray a mass like this in the mediastinum representing a lymph node enlarged by metastasis from a bronchiogenic carcinoma?

DR. HOLMES: Yes.

DR. BREED: A small tumor with a large lymph node in this location is a perfectly good explanation?

DR. HOLMES: Yes.

DR. BREED: I am glad of that because that is what I should like to put as number one: an enlarged mediastinal lymph node caused by metastasis from a bronchiogenic carcinoma in the left upper bronchus. You have heard all the reasons. I do not believe that it was an aneurysm. In the first place if it were on an arteriosclerotic basis one would expect it to be calcified. The location is against its being syphilitic and, moreover, the Hinton test should have been positive.

DR. HOLMES: I might give one more clue. If it was an aneurysm, it was located in just the right place to produce a good tracheal tug.

DR. BREED: I do not believe that there was a tracheal tug. That statement was probably produced by the fervor of someone trying to make a diagnosis. Maybe he was backing an aneurysm. You have done that. Each of us has backed his own horse. If it was not a metastatic lymph node, I have not the foggiest notion what it was.

DR. MALLORY: Dr. Cordero, can filariasis be generalized enough to give mediastinal or pleural involvement?

DR. FERNANDO CORDERO: No. In the cases that we see in my country (Guatemala), the disease is cutaneous, with enlargement of only the superficial lymph nodes, especially the inguinal. We performed 60 or 70 autopsies on patients with filariasis and were unable to find any kind of microscopic lesions in the deeper tissues of the body, except for a few cases in which the infection had been present for five to ten years. In these, the tracheal lymph nodes were enlarged. Furthermore, all these cases of filariasis had characteristic blood changes. In 99 per cent an eosinophilia of at least 30 per cent was found. In this case eosinophilia was not present. Therefore I do not believe that it was filariasis.

DR. ADAMS: I should like to ask Dr. Holmes if he can state in which direction the trachea is displaced. It is to the right in the anteroposterior view. If he can make a positive statement regarding the displacement of the trachea in the lateral view, this might give a conclusive clue.

DR. BREED: I do not recall that the trachea was displaced.

DR. ADAMS: Am I correct in believing that the lower end of the trachea at the carina is displaced to the right in the lateral view?

DR. HOLMES: Yes.

DR. ADAMS: Is the trachea displaced in any other direction?

DR. HOLMES: What was said in the report?

DR. BREED: It did not say. No one said it was

displaced to the right in the report, but it obviously is.

DR. ADAMS: If the trachea were displaced anteriorly as well as laterally the mediastinal mass, to be an aneurysm, would have had to extend under it from a lateral origin, which it obviously does not do. Therefore, if the trachea is displaced anteriorly, I believe this must have been a carcinoma of the lung, as Dr. Breed has stated.

DR. HOLMES: I think the trachea is displaced anteriorly.

DR. ADAMS: It would be impossible for an aneurysm arising in the ascending aorta to displace the trachea anteriorly.

DR. HOLMES: That is an excellent point.

CLINICAL DIAGNOSIS

Aneurysm of aorta.

DR. BREED'S DIAGNOSIS

Carcinoma of left upper-lobe bronchus, with metastasis to mediastinal lymph node.

ANATOMICAL DIAGNOSIS

Bronchiogenic carcinoma of left upper lobe, with peribronchial and peritracheal metastases.

PATHOLOGICAL DISCUSSION

DR. MALLORY: There was a great deal of backing and filling on the part of all the people forced to attempt to make a diagnosis on this case. The patient was referred to Dr. Robert Linton, with the question whether it was an aneurysm that ought to be wired, and to Dr. Richard Sweet with the question whether it was a tumor that ought to be explored. It was evidently decided to explore, and Dr. Sweet operated. On opening the thorax, he came down upon a large mass of lymph nodes beside the trachea. He took a biopsy specimen, which showed frank carcinoma. Through this incision he was able to palpate the left upper lobe and found the primary tumor.

DR. HOLMES: One other statement that might be brought out now is that following the biopsy the patient was given 3000 r of million-volt x-ray therapy front and back, and you can see by comparing the first plate and the last one that there was no appreciable effect on the tumor. If we had used that as a therapeutic test we should have decided that it was an aneurysm.

DR. BREED: What was the x-ray diagnosis?

DR. HOLMES: I never was very positive. I believe that I was a little more in favor of aneurysm than of tumor. When you go back over them, there is enough evidence in the x-ray films to have made a correct diagnosis, but I did not do it.

CASE 29262

PRESENTATION OF CASE

A fifty-six-year-old laborer entered the hospital because of severe lower abdominal pain and constipation.

The patient was in good health, having never been severely ill, until twenty days before admission when, after no particular change in diet, he began to have severe low abdominal pain, referred chiefly to the left of and below the umbilicus. This pain continued in episodes of increasing severity. He then became constipated, being unable to have a bowel movement without a cathartic or enema. On one occasion he reported passing dark-red blood by rectum. He developed anorexia, and because of this the intake of foods and fluids had been markedly diminished. He had lost about 35 pounds during the present illness.

Six days prior to entry the lower abdominal pain and anorexia increased in severity. Thirty-six hours before admission the patient began to vomit; at first the vomitus was a bitter yellowish fluid but during the few hours before admission it changed to a foul-tasting, fecal-smelling, brownish material. He had taken little by mouth during the previous week and had had no results from enemas for several days, although he had continued to pass gas by rectum up to the time of admission. On the day of admission he vomited continually; this relieved the pain in the left lower quadrant for a few minutes, but it then came back in waves about four minutes apart. On the day of admission, the patient believed that his abdomen was larger than it had been.

The family and past histories were noncontributory.

Physical examination showed a tired, dehydrated, co-operative man who was obviously in distress from pain and repeated vomiting. The heart and lungs were normal. The abdomen was somewhat distended. Peristalsis was good, sometimes rushing, but the sounds were not high pitched. No masses were felt. There were tenderness and questionable spasm to deep palpation in the left lower quadrant. Palpation in this region caused pain all over the abdomen, especially in the right upper quadrant. After one examination, there was rushing peristalsis ending in fecal vomiting five minutes later. Rectal examination and proctoscopy for a distance of 35 cm. were not remarkable.

The blood pressure was 100 systolic, 85 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red-cell count of 5,870,000, with a hemoglobin of 80 per

cent, and a white-cell count of 9900, with 85 per cent neutrophils. The urine was normal. One stool was guaiac negative.

A flat plate of the abdomen revealed several air-filled loops of small intestine that appeared slightly wider than usual. There were several areas of calcification measuring 1 cm. in diameter in the right midabdomen above the fifth transverse process.

When examined a few hours after admission the patient complained of abdominal pain, mostly paraumbilical and to the left, with pain in the back or shoulders and no abdominal discomfort or pain above the belt line. The abdomen was held in some voluntary spasm, but the right rectus muscle seemed tighter than the left. Tenderness was diffuse. Peristalsis was not particularly active except at five-minute periods, when he complained of colic. At these times, tinkles were heard but no rushes. The colic seemed to be paraumbilical and to move from left to right. The patient vomited fecal material, and a stomach tube produced 300 cc. of such material. A strenuous two-hour attempt to pass a Miller-Abbott tube through the pylorus was unsuccessful. At the end of this procedure the patient was tired out and the Miller-Abbott tube was replaced by a Levine tube.

Despite intravenous glucose and saline infusions and morphine, the patient grew more restless and the pain and vomiting occurred oftener. The pulse and respirations rose to 180 and 58 respectively and the temperature dropped to 97°F. approximately twelve hours after admission. The patient became slightly disoriented and deeply cyanotic, and the abdomen became quiet. The extremities were cold and clammy. The heart sounds were weak and of poor quality, and no blood pressure could be obtained. He died fourteen hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. WALLACE: This patient had the classic symptoms of intestinal obstruction—abdominal cramps, fecal vomiting and obstipation. Colicky pain in the lower abdomen should have its origin in the large bowel, and with this, in a man of his age, pain and tenderness in the left lower quadrant are most commonly caused by diverticulitis of the sigmoid. The absence of a mass and no elevation of temperature or white-cell count should rule out this lesion, and in addition the x-ray films show no dilatation of the cecum or even an abnormal amount of gas anywhere in the colon. With such striking symptoms of intestinal obstruction these findings should eliminate the large bowel as the source of his trouble. The frequency of fecal vomiting greatly favors small-bowel obstruction, since, in general,

the rule holds—the higher the obstruction in the intestine the oftener the vomiting. Dilated loops of small bowel by x-ray substantiate the diagnosis of small-bowel obstruction.

We have no evidence to suggest inflammatory disease as a cause of obstruction and there is no history of previous operation, which might have caused adhesions. Externally there was no apparent hernia, which eliminates the commonest cause of small-bowel obstruction. The calcified areas shown by x-ray are presumably healed tuberculous nodes, and late obstruction might be caused by adhesions to one of these. An adherent Meckel's diverticulum is a rare cause of small-bowel obstruction, but complications from Meckel's diverticulum almost always occur before middle life. The history and sequence do not suggest regional ileitis. Intussusception can happen late in life and is usually associated with a polyp or benign tumor, such as lipoma, fibroma or leiomyoma. Indeed, these benign tumors may cause obstruction without this complication. Volvulus in the previously unexplored abdomen does not commonly occur in the colon, and much less so in the ileum or jejunum. Internal hernia occurs in various places and cannot be ruled out. The absence of a high white-cell count should rule out gangrene of the intestine or mesenteric thrombosis.

Foreign body is another possibility. It most commonly is a chicken bone, and one large enough to become stuck and cause obstruction. Such a bone might show by x-ray, but a fishbone or toothpick probably would not. Primary lymphoma of the bowel does occur and does advance to fatality without superficial nodal involvement, but in the advanced state a mass is usually palpable. Incidentally, a solitary lymphoma of the intestine should always be resected since it is sometimes a localized process that is not related to a generalized disease. Carcinoma of the small bowel can never be ruled out without careful barium studies, which in this patient were impossible.

The episode of pain, four hours before death, followed by diffuse tenderness, spasm and loss of peristalsis and then by circulatory collapse and death, suggests perforation of the bowel with massive peritoneal insult. I cannot make a diagnosis

of the cause of the obstruction but the likely possibilities are foreign body, carcinoma and lymphoma.

CLINICAL DIAGNOSES

Diverticulitis of sigmoid, with perforation.
Acute generalized peritonitis.

DR. WALLACE'S DIAGNOSES

Small-bowel obstruction, due to foreign body, carcinoma or lymphoma, with perforation.
Acute generalized peritonitis.

ANATOMICAL DIAGNOSES

Adenocarcinoma of transverse colon, with perforation.
Acute generalized peritonitis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Dr. Wallace was correct in his diagnosis of perforation of the intestine with generalized peritonitis. The peritoneal cavity contained about 500 cc. of foul-smelling, creamy pus distributed from beneath the diaphragm to the pelvis. Some of the loops of small intestine were adherent to each other by strands of fibrin. The duodenum and jejunum were markedly dilated, but the ileum, cecum and ascending and transverse colons were not. The perforation was in a small annular constricting carcinoma of the transverse colon just proximal to the splenic flexure; it had already been almost completely sealed by the surrounding exudate. The presence of so much fibrin and frank pus and the partial sealing of the perforation indicate that the perforation had occurred before admission. Ordinarily an obstructing carcinoma in the region of the splenic flexure causes extreme dilatation and often perforation of the cecum. The fact that the cecum was not distended roentgenologically led Dr. Wallace away from a diagnosis of large-bowel obstruction. The right colon and ileum were almost certainly dilated before the perforation, but by the time the patient entered the hospital they had been decompressed by the perforation.

AMERICAN MEDICAL ASSOCIATION

ALTHOUGH the annual scientific meeting of the American Medical Association was given up this year because of transportation and other difficulties resultant from the war, it is still necessary to conduct its affairs in an orderly manner. Therefore the House of Delegates was called together in Chicago on June 7, 8 and 9. This meeting was remarkable in that the attendance of delegates was approximately one hundred per cent. Every state delegation was filled, and every section delegate was present—only those from Alaska, Puerto Rico, Canal Zone, Philippines and Hawaii were absent. This is a truly remarkable

record in these difficult times, and a sure indication of how seriously the delegates respect their appointments.

Much routine business was transacted. Perhaps the most significant action was the setting up of the Council on Medical Service and Public Relations. This council is charged with the general consideration of all matters relating to medical service and their interpretation to the public. It will have the benefit of the work of both the Bureau of Medical Economics and the Bureau of Legal Medicine, and will be made up of one member from each of nine areas of the country so that it should well represent and amalgamate the great divergence of local opinion regarding such matters. To tie it in with the administration of the American Medical Association, the president, the immediate past president, the secretary and a representative of the Board of Trustees are members *ex-officio*. The House did not look with favor on the establishment of an office in Washington, D. C.

The Secretary reported an increase in membership of 2040 during the past year, in spite of the fact that a decrease had been predicted. In the last ten years the membership has grown from 97,111 to its present figure of 122,741. This growth is believed to be proportionately larger than the increase in the number of physicians in the United States and seems to refute the rumor that the American Medical Association is losing prestige among the physicians of the country.

The House was addressed by Surgeon General Kirk of the United States Army, who told about conditions in Africa and on other fronts, and General Grant, chief of the Air Medical Corps, told of the excellent training men in this arm of the service are receiving.

On Tuesday evening, Dr. Roger I. Lee, chairman of the Board of Trustees, presented the retiring president, Dr. Fred W. Rankin, with the President's Medal, following which the incoming president, Dr. James M. Paullin, of Atlanta, Georgia, was inducted into office. Much to the delight of the Massachusetts delegation, Dr. El-

liott P. Joslin was invested with the Distinguished Service Medal, which he accepted with his usual simplicity and grace. Dr. Paullin's address had to do with postwar conditions and was provocative of much thought. Dr. Herman L. Kretschmer, who has been treasurer for the past ten years, was made president-elect.

CONCERNING TROUSER CUFFS

A RECENTLY published pronouncement of the War Production Board in Washington has at last partly alleviated one of the more bizarre hardships of war. We may still go without tires, gasoline and sirloin steaks; we are still engrossed in the problem of keeping up with the changing styles in air-raid warning signals; we must pay taxes, buy bonds and shop unsuccessfully for that vanishing American, the potato; but we may again have cuffs on our pants. That is, if we are short enough, since a "32-inch waist regular" is allowed only a 35-inch inseam. So far as all recent advices are concerned, the restrictions on getting pants "on the cuff" remain the same.

The cuff restriction has already accomplished its main purpose, according to the WPB, since enough excess wool cloth has been recovered from 19,000,000 pairs of pants to make an extra 300,000 wool garments, also without cuffs. Such is the labor shortage, however, that it is still a grave question whether tailors can be found in sufficient numbers to sew together the amputated cuffs, like mink skins, in order to produce the extra 300,000 wool garments. Still later reports, this time from New Haven, indicate that the back rooms of tailor shops there are piled high with potential moth food—this mandatory material—awaiting some form of future usefulness. To a humble editor, it seems as if a more effective method of excess wool gathering would be the practice of collection at the source, like the less painful forms of taxation, rather than the making up so many million pairs of superfluously materialized pants, only to have this mass-scale *Schnitzenfest* to conform to the federal order.

Had we our hygienic-minded way with some of these affairs of greater or less importance, this sordid boon of turned-up pants would never have been granted even to the short men. In the first place, let short men recall that optical illusion by which cuffs on the pants, instead of an unbroken sweep of well-creased trousers, can make them look still shorter; and in the second place, let men of all stature remember trouser cuffs for the dirt traps that they are, and shun them hereafter and forever. True, trouser cuffs may have their uses, like catch basins, street gutters and grease traps, and many a time they have served as repositories for used matches, cigarette ashes and even burned-out butts by bashful youths caught smoking in a spotless parlor; but most of us prefer not to carry our dust bins as integral parts of our clothing.

MEDICAL EPONYM

WERLHOF'S DISEASE

The first reference to this syndrome was made by Paul Gottlieb Werlhof (1699-1767) in a footnote to his treatise "De variolis et anthracibus [Smallpox and Carbuncles]," published at Brunswick in 1735. The following is a translation of the passage in the third chapter of the essay, as printed in the second volume (page 539) of his posthumously collected works (*Opera Medica*, 1775-1776):

Might it not be supposed that these macules, having such an intimate association with hemorrhages, occur in conjunction with smallpox, not as a symptom but as a disease *sui generis*? I am led to this conclusion from having frequently observed this *morbus haemorrhagicus maculosus* in previously healthy persons without smallpox or any other acute disease either during the course of an intermittent fever or occasionally without fever. The pulse is at times small, quick and frequent (especially if there is a fever) and often irregular in force, and there is marked prostration until the macules gradually begin to fade, the bloody exudations cease and complete recovery ensues. For example, five years ago I saw this affection break out spontaneously in a ten-year-old girl, with profuse hemorrhages of foul or clear, black or serous blood from the nose, gums and throat, and in the vomitus, stools and urine, together with other variable symptoms, such as syncope and chills, while the macules, growing blacker and more abundant, gradually spread over the whole body. Although so much of the vital fluid had been lost that no strength seemed to be left in the pale, enfeebled body, nevertheless Nature with

the aid of my medicines fought, as Lucin says with all the blood that remained, and finally triumphed over the disease. After eleven days the spots disappeared, the hemorrhages ceased and there was gradual resumption of health, which has persisted up to the present time

R W B

DEATHS

CORIAT—ISADOR H. CORIAT, M.D., of Boston died May 26. He was in his sixty-eighth year.

Dr Coriat received his degree from Tufts College Medical School in 1900, and later studied philosophy under William James at Harvard. From 1900 to 1905 he was a resident physician at the Worcester State Hospital from 1905 to 1919 a member of the neurological staff of the Boston City Hospital and from 1919 to 1928 consulting neurologist at the Chelsea Memorial and Beth Israel hospitals.

He was a trustee, librarian and chairman of the Educational Committee and an instructor of the Boston Psychoanalytic Institute. He founded the Boston Psychoanalytic Society, and was its president from 1930 to 1932. He had twice served as president of the American Psychoanalytical Association, once in 1924 and again in 1936. He was a member of the Massachusetts Medical Society and the American Medical Association.

ELLIOTT—ALFRED ELLIOTT, M.D., of Middleboro died March 1. He was in his seventy-second year.

Dr Elliott received his degree from the College of Physicians and Surgeons of Baltimore in 1900. He served on the staff of St. Luke's Hospital. He was a member of the Massachusetts Medical Society and the American Medical Association.

RICHMOND—SIMON RICHMOND, M.D., of Boston died February 5. He was in his seventy-first year.

Dr Richmond received his degree from Harvard Medical School in 1897. He was a member of the Massachusetts Medical Society and the American Medical Association.

YOUNG—ANNIE R. YOUNG, M.D., of Waltham died March 16. She was in her eightieth year.

Dr Young received her degree from Tufts College Medical School in 1911. She was a member of the Massachusetts Medical Society and the American Medical Association.

CORRESPONDENCE

SUPPLEMENTARY FOOD RATIONS

To the Editor: Many physicians are puzzled by conflicting statements and lack of authoritative opinions on special rationing needs of the sick. Since these problems are faced by the medical staff of the Boston City Hospital in the care of outpatients and, at times, of discharged house patients the following plan was worked out for their guidance. It is presented here in the hope that it will be helpful to the profession at large.

The basic rations of processed foods (blue points) have been found intrinsically adequate in health as well as in disease. Practically, however, because fresh vegetables and fruit products are scarce or expensive, a few certificates have been issued for the always available and less expensive processed foods. The allowance has ranged from 8 to 20 pounds of processed foods, or up to 200 points per month. The average was 80 points per month.

On the other hand, several groups of patients need more of meat, fish, fats and cheese (red points) than is allowed by the basic ration. The most important are patients with diabetes, chronic gastrointestinal disorders (such as chronic ulcerative colitis, peptic ulcer and gastrointestinal resection), pernicious anemia, cirrhosis of the liver, hypoproteinemia and pregnancy. The average certificate issued was for 12 or 13 pounds of animal foods per month, 3 to 4 pounds in excess of the basic ration. Only an exceptional case required over 16 pounds. It is believed that 30 pounds of animal foods represents the absolute maximum that may be judiciously prescribed.

BOSTON CITY HOSPITAL Ration Supplement Certificate

Applicant may attach this certificate to CPA Form K315

FIGURE 1

Most pregnant women and working or growing diabetic patients fall in this category. Unless great dependence is placed on the protein and fat of milk, all these patients need ration supplements. Controversy over the optimum fat intake of diabetic patients is the source of many of the conflicting opinions, but it seems fair to allow them to continue the diet to which they have become accustomed rather than to order substitution of unrationed commodities which may be restricted tomorrow. A table of the food requirements of such patients has been completed to assist the hospital staff in certifying ration needs (Table 1).

Many statements sent to rationing boards by physicians have been invalid because of failure to state that unrationed foods cannot be used with the reason why. A copy of the temporary form used by the Boston City Hospital, which satisfies all the present requirements of the OPA, is appended (Fig. 1). On the form, under "Processed Foods," the exact type must be specified. All unused spaces of the certificate are cancelled with an X. The hospital record contains a duplicate of this

NOTICES

AMERICAN CONGRESS OF PHYSICAL THERAPY

The twenty-second annual scientific and clinical session of the American Congress of Physical Therapy will be held September 8-11, at the Palmer House, Chicago. The annual instruction course will be held from 8:00 to 10:30 a.m., and from 1:00 to 2:00 p.m. during the days of September 8, 9 and 10, and will include a round-table discussion group from 9:00 to 10:30 a.m., Thursday, September 9. The scientific and clinical sessions will be given on the remaining portions of these days and evenings. A feature will be an hour demonstration showing technic from 5:00 to 6:00 p.m. during the days of September 8, 9 and 10. All these sessions will be open to members of the regular medical profession and their qualified aids.

For information concerning the instruction course and program of the convention proper, address the American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago.

1943 GRADUATE FORTNIGHT

The 1943 Graduate Fortnight of the New York Academy of Medicine will be held from October 11 to 22. The current topic is "Disorders of the Digestive Tract."

There will be a carefully integrated program that will include morning panel discussions, afternoon hospital clinics, evening addresses and exhibits.

The following subjects will be included: the physiology of the gastrointestinal tract; emotions and gastric function; a critical review of gastroscopy; diagnosis and treatment of benign and malignant lesions of the stomach; the pathologic physiology of gastric and duodenal ulcer; recent advances in the therapy of peptic ulcer; disorders of the gastrointestinal tract in children; surgical aspects of congenital anomalies of the gastrointestinal tract in children; postcholecystectomy syndrome and its treatment; recent advances in the surgery of the pancreas; present status of regional enteritis and ulcerative colitis; the sulfonamides in gastrointestinal diseases; amebiasis and the flagellate diarrheas; problems of immunity to bacillary dysentery; the management of acute intestinal

PHYSIOLOGIC CONSIDERATIONS IN THE TREATMENT OF NEPHRITIS*

GEORGE W. THORN, M.D.†

BOSTON

IT IS a very great honor for me to have been given this opportunity of presenting the fifty-fourth Shattuck Lecture. As you well know, this lectureship was founded in the year 1854 by a gift from the estate of George C. Shattuck, the elder, son of Benjamin Shattuck, a medical practitioner in Templeton, Massachusetts, and father of George C. Shattuck, the younger, the fourth Hersey Professor of the Theory and Practice of Physic. In earlier years at Harvard College it was the custom for all newly appointed professors to deliver an oration on taking office, and I feel that my lecture this evening corresponds in many ways to that earlier custom. With this in mind, I have selected a subject for discussion that has been of particular interest to several former professors of the theory and practice of physic. As the result of their observations we have obtained a clear picture of the pathologic changes that occur in nephritis and a good understanding of its clinical course.

This evening I wish to discuss particularly a rational basis for the treatment of the metabolic disturbances that occur in patients with renal insufficiency. Patients with kidney disease constitute a large and important group in both private and hospital practice. In the past it has been the custom to discuss therapy largely on the basis of the type of renal lesion. Such an approach usually resulted in prolonged discussion as to the nature of the renal disease and in little consideration for the specific correction or improvement of the presenting metabolic disturbances. A brief survey of the paragraphs relating to therapy in nephritis as recorded in standard medical textbooks is sufficient to impress one with the confusion that exists at present in this field. Medical students and house

officers are not infrequently bewildered as to how to proceed in attempting to correct the physiochemical disturbances that occur in patients with nephritis.

Contact with the clinical manifestations of renal disease soon impresses one with the fact that nearly every type of metabolic disturbance that is known to occur in conjunction with renal disease may occur in the presence of any specific type of renal lesion, although, as we know, particular metabolic disturbances are encountered with much greater frequency in association with certain types of renal lesions. This consideration might lead one to suspect that it would prove to be simpler and certainly more helpful if therapy were dictated primarily by the nature of the metabolic disturbance rather than by the type of pathologic change in the kidney. Thus the measures used in combating azotemia would be determined by such facts as whether azotemia was associated with dehydration, hypoproteinemia, edema or hypertension rather than whether azotemia was a consequence of acute nephritis, chronic glomerular nephritis, pyelonephritis or congenital cystic disease of the kidneys. We have a precedent for this approach in the methods employed in the treatment of diabetic acidosis and coma. In this disease hyperglycemia, acidosis, dehydration and lipemia are treated as such, and in outlining therapy little attention is given to the nature of the underlying pathologic changes. On the whole these patients do well because we have developed some degree of skill in estimating the *quantity* as well as the *quality* or type of therapeutic agents employed. Quantitative considerations play an extremely important role in the treatment of the metabolic disturbances associated with nephritis, since the body under these circumstances is so limited in its ability to compensate for an excess or deficiency of the indicated therapeutic agents. Hence it is not

*The Shattuck Lecture delivered at the annual meeting of the Massachusetts Medical Society, Boston, May 29, 1943.

Hersey Professor of the Theory and Practice of Physic, Harvard Medical School, physician in chief, Peter Bent Brigham Hospital.

enough to know *what to use*—one must also have a very clear idea as to *how much to use!*

At this time it might be helpful to review a few basic physiologic principles, a knowledge of

TABLE 1. *Basic Dietary Requirements for Health.*

Water, sufficient to provide a urine volume of approximately 1000 cc daily
Calories, sufficient to maintain weight
Protein, approximately 1 gm per kilogram per day
Essential minerals and vitamins

which is essential to the intelligent application of the therapeutic measures indicated in the treatment of patients with nephritis. We know that

1 gm. per kilogram daily is adequate. Evidences of specific amino acid deficiencies may appear on diets of lower protein content unless the particular proteins used are complete in essential amino acids. The daily requirements for the various minerals and vitamins have now been fairly well established.¹

Since these four basic dietary requirements are the minimum necessary under optimal conditions, there is every reason to believe that in the presence of disease they will certainly not be decreased; in fact, the requirement of certain of them may be greatly increased. Hence there is little justification for a therapeutic regimen in the treatment of patients with renal insufficiency that permits

FIGURE 1. *Weight Curve in a Patient with Glomerular Nephritis.*

in order to maintain health the body must be provided with at least the four essentials (Table 1).

Under most conditions if water intake is sufficient to provide for a urine volume of 1000 cc. daily, renal function may be carried on quite satisfactorily. It is obvious that in the presence of renal insufficiency more water may be required than under normal conditions, since the kidneys' ability to concentrate urine may be markedly impaired.

The ideal diet for health is one that provides sufficient calories for maintenance of optimum weight. In undernourished patients, the caloric requirement will be considerably increased until optimum weight has been attained; in children, calories sufficient to permit normal growth must be provided. For adults, a protein allowance of

the exclusion or significant reduction in any one of these essentials for any continued period of time.

Difficulty in estimating the caloric requirement of patients with renal insufficiency. In health one can readily establish the caloric requirement of a subject by following changes in body weight in response to the ingestion of a diet of varying caloric content. In childhood, the added factor of growth must be considered. In most diseases the caloric requirement can also be estimated from changes in body weight. There are, however, at least two groups of diseases that provide notable exceptions to this rule: diseases associated with impaired intestinal absorption, that is, enteritis, sprue, cirrhosis of the liver and so forth; and cardiac and renal failure with edema.

In the first group of diseases weight loss may occur despite a normal caloric intake because of poor or impaired absorption from the gastrointestinal tract. In the second group weight gain may occur despite an inadequate caloric intake because of excessive salt and water retention. Thus in patients with nephritis it is frequently impossible to estimate the adequacy of caloric intake by following changes in body weight. This is well illustrated by the marked fluctuations in body weight that were observed in a patient with glomerular nephritis who was maintained on a constant diet of adequate caloric intake (Fig. 1). The patient had been ill for approximately ten days before entering the hospital. On admission this patient weighed 48.2 kg. and was markedly edematous. His daily caloric intake was 2100 calories. During the first ten days after admission a weight loss of over 6 kg. (approximately 13 lb.) was observed. This occurred despite the intake of adequate calories for weight maintenance. On the tenth day there was no edema present, and the patient appeared distinctly undernourished. Forty days later this patient weighed 48 kg., a gain of 13 lb. on the same caloric intake, that is, 2100 calories daily, and at that time there was no edema present. Thus on a constant diet adequate for growth this patient first lost weight, then gained, the loss being occasioned by excretion of fluid; the gain in this instance was largely new tissue.

Estimation of water balance. Because edema and dehydration are frequent complications of nephritis, considerable emphasis is placed on measurement of water balance. Unfortunately, to most physicians the term "water balance" indicates

TABLE 2 Determination of Fluid Balance

INTAKE	OUTPUT
Liquids	Urine
Water content of solid food	Feces
Water resulting from oxidation of protein, carbohydrate and fat	Insensible water loss
	Perspiration
	Abnormal water losses (saliva, sputum, draining fistulas and so forth)

simply the relation that exists between the quantity of liquids ingested and urine output! It is obvious from a study of Tables 2, 3, 4 and 5 that one cannot interpret water balance on the basis of the difference between fluid intake and urine output. Fortunately there are fairly reliable clinical signs that indicate changes in water balance, that is, increasing edema, dry skin, dry tongue, enophthalmos and so forth since under most circumstances it is impossible or impractical to make the elaborate measurements necessary for accurate determination of water balance.

In relation to edema it is important to emphasize the fact that the retention of additional fluid in the extracellular compartment is almost totally dependent on the retention of sodium.² Thus, it

TABLE 3 Determination of Sensible and Insensible Water Loss (overnight weight loss under standard conditions).

Weight of patient at 9 p.m.	52.5 kg

Difference	0.3 kg
$0.3 \text{ kg.} \times \frac{24}{12} = 0.6 \text{ kg. insensible water loss in a 24 hour period}$	

may be stated that without a source of sodium there can be little retention of ingested fluid. This can easily be proved by drinking a large quantity

TABLE 4 Calculation of Water of Oxidation

$120 \times 1.0 = 120 \text{ gm.}$	
Total	268 gm. water

of water and restricting sodium chloride to 15 gm. or less per day. On this regimen little or no increase in body weight will be observed. If, on the other hand, one drinks adequate quantities of water and ingests large quantities of salt, excessive weight gain will occur and edema may become apparent. For the patient with nephritis it is well to emphasize the fact that quantities of sodium chloride as small as 2 to 5 gm. daily may present a tremendous excess for renal excretion and thus

TABLE 5 Calculation of Fluid Balance

Diet Protein 70 gm.	carbohydrate 200 gm.	fat 120 gm.	
INTAKE			OUTPUT
Fluids	1500 cc	Urine volume	1150 cc

Weight of patient at beginning and end of 24 hour period revealed a gain of 0.1 kg. (100 cc.)			

induce an effect equivalent to 20 to 30 gm. of sodium chloride daily in normal subjects.

A factor that also may affect water balance in female patients with nephritis is the salt-and-water retention that occurs normally during the three to seven days prior to the onset of menstruation.³

Normal women are known to retain excessive quantities of salt and water during the week immediately preceding the onset of menstruation (Fig. 2). With the onset of menstruation, a diuresis is frequently observed and the excess fluid is eliminated. Female patients with nephritis may

ciently as can normal subjects, since the ability of the kidney to form ammonia from urea may be limited. Sodium and other fixed bases are drawn from the body and excreted in order to help neutralize acid end products excreted by the kidney. This may result in a severe depletion of the alkali

FIGURE 2. The Normal Premenstrual Gain in Weight Associated with Sodium Retention.

be expected to exhibit this same phenomenon during the years of ovarian activity. In the presence of a fundamental derangement that predisposes to fluid accumulation such as nephritis, however, one may expect a much greater total retention of sodium, chloride and water. Female patients afflicted with chronic nephritis have been suspected not infrequently of having recurrent exacerbations of their disease, as evidenced by the appearance of edema and a moderate rise in blood pressure during the phase of premenstrual retention of sodium, chloride and water (Fig. 3).

Acid-base balance. In normal subjects an equilibrium exists in which the acid ash of the diet and the acid end products of metabolism are eliminated with the use of a minimum quantity of fixed base—principally sodium. This is accomplished in part by the ability of the lungs to ventilate carbon dioxide, in part by the ability of the kidneys to form the base ammonia from urea, which is a waste product, and in part by the ability of the kidneys to eliminate an acid urine in the presence of a glomerular filtrate that is alkaline in reaction (Table 6). Patients with nephritis, however, can no longer conserve base as effi-

ciently as can normal subjects, since the production of acid metabolites cannot be decreased significantly in patients with renal disease who are resting in bed and who do not have fever, only two approaches

TABLE 6. Acid-Base Balance.

The body must be prepared to care for an excess of acid resulting from:	
End products of metabolism	
Acid-ash diet	
Several mechanisms are utilized in caring for an excess of acid:	
Buffer system of the blood	
Ventilation of carbon dioxide	
Excretion of an acid urine	
Formation of ammonia by the kidney	

are open by which one may conserve the base reserves of the body: decreasing the acid ash of diet by ingesting a diet of neutral or alkaline ash composition; and administering an excess of alkali (preferably sodium) to provide for the increased renal needs of fixed base. The former approach may be employed at all times; the latter is usually contraindicated in the presence of edema.

Aluminum hydroxide may be added to milk or taken with food; by so doing a great reduction

in phosphorus absorption can be demonstrated (Fig. 4). By employing aluminum hydroxide one is able to use foods of high nutritive value—for example milk—that naturally contain large quan-

and the serum carbon dioxide combining power gives one a fairly accurate indication of the serum base under most circumstances and permits one to decide whether sodium chloride or sodium bi-

FIGURE 3. *Changes in Weight during the Menstrual Cycle in a Nephritic Patient.*

ties of fixed acid, and that without the addition of aluminum hydroxide, would add to the burden placed on the kidney.

Acid-base composition of blood plasma. Detailed analysis of the changes in acid-base composition of blood plasma that may occur in patients with renal disease has been presented by Peters and his co-workers.⁴ The physiologic implications that arise in relation to these changes have been clearly outlined by Gamble.² It is obvious that in the treatment of patients with renal insufficiency, just as in the treatment of patients with severe diabetes, one must have available laboratory facilities for certain chemical determinations. It is essential to limit the necessary determinations to those that can be carried out in most general hospital laboratories if the application of successful treatment is not to be limited to a few research centers. It would appear desirable to be able to determine the blood urea nitrogen or nonprotein nitrogen level of the blood, the total serum protein, the serum chloride and the serum carbon dioxide combining power. The albumin-globulin ratio is not essential for guiding therapy, since it is safe to assume that all patients with nephritis probably have some reduction in serum albumin level. A knowledge of the serum chloride level

carbonate or both should be administered or withheld (Fig. 5). In summary, one should be able to guide therapy efficiently and effectively in most cases if the following chemical determinations can be performed promptly: blood urea nitrogen or nonprotein nitrogen, total protein, serum chloride and serum carbon dioxide combining power.

Role of serum protein. An understanding of the composition and role of the serum proteins is essential in considering the treatment of patients with nephritis. The relation of albumin to globulin in the serum is well known, and the changes in colloid osmotic pressure that occur with changes in the relative quantities of these two proteins are evident (Fig. 6). A striking reduction in serum colloid osmotic pressure may occur in the presence of a normal total serum protein level as a consequence of a decrease in the albumin-globulin ratio. This latter change may be observed frequently in patients with acute nephritis in whom a rise in globulin frequently conceals a reduction in albumin. Thus despite a normal total serum protein level one may have a greatly reduced serum colloid osmotic pressure.

Longcope's⁵ studies have revealed that patients with acute nephritis of severe degree usually have a striking reduction in serum albumin level and a

corresponding rise in serum globulin. Patients with less severe renal damage show similar but less striking changes. Recovery from acute nephritis is usually associated with a rise in serum albu-

min. Since in most cases it is not possible to obtain a striking increase in serum albumin level with high-protein feeding or amino acids by mouth or intravenously, it is apparent that serum albumin

FIGURE 4. The Effect of Aluminum Hydroxide Therapy, Diet Being Constant.

min and a fall in serum globulin. It therefore appears that most patients with renal impairment,

administration is the only effective means of compensating for this deficiency.

Because of its apparent rapid utilization, serum albumin administration in doses available for chemical use should not be expected to increase the level of serum albumin. It can be estimated from studies on animals fed protein-deficient diets that in man an increase of 1 gm. in the concentra-

FIGURE 5. The Acid-Base Composition of Blood Plasma.

either acute or chronic, manifest some degree of serum albumin depletion, and therefore one of the most characteristic disturbances in metabolism associated with renal disease is hypoalbuminemia.

tion of serum albumin or a total increase of 30 gm. in plasma albumin on the basis of a plasma volume of 3000 cc. (Table 7) may be reflected in the entire body as necessitating the retention of 750 gm. of protein (Fig. 7).⁶ The concept that an equilibrium exists between the body protein in general and serum albumin aids in understanding

TABLE 7. Calculation of the Total Quantity of Protein in Plasma.

Plasma volume	× protein concentration (gm. per 100 cc.) = Total protein	
100		
<i>Example:</i>		
3000	× 7.0 gm. = 210 gm.,

of which two thirds is albumin, that is, 140 gm.		

why it is difficult, if not impossible, to increase appreciably the serum albumin level with the quantities of intravenous protein that can be given safely.

In administering protein intravenously to patients with renal insufficiency it appears that the

large dose in patients with hypertension or in patients with cardiac enlargement. It is possible, as a result of the reduction in edema and azotemia that frequently follows the administration of parenteral fluids and albumin solution, that the digestion and absorption of ingested protein and

FIGURE 6. Serum Proteins and Colloid Osmotic Pressure.

chief benefit is derived from the temporary increase in colloid osmotic pressure, the resulting in-

crease in the synthesis of serum albumin from ingested protein may be improved, and this improvement in

FIGURE 7. Diagram Showing That to Increase Serum Albumin 1 Gm. Requires the Retention of 750 Gm. of Protein.

creased hydemia, the increased glomerular filtra- turn may be reflected by a gradual rise in serum tion and hence the decrease in edema and azo- protein concentration. The total plasma content of protein may also play an important physiologic role. We are accustomed to assume that a value of 7 gm. of serum protein today and a similar value observed one or

two weeks hence represent equivalent quantities of serum protein in the body. Actually this may not be the case, since plasma volume may have increased or decreased in the meantime, and thus there may have been a considerable increase or decrease in the *total quantity of plasma protein*. This can be demonstrated by injecting slowly a measured quantity of serum albumin intravenously, under which circumstance little or no rise in serum albumin level will occur, but a very great increase in plasma volume can be demonstrated⁷ and of course the total quantity of plasma protein is temporarily increased. That such changes might occur spontaneously in patients with renal insufficiency is possible. It is of interest to note how frequently diuresis attended by no increase in serum albumin level is assumed to indicate that no change in serum protein could have occurred. Such a deduction is obviously subject to error unless plasma-volume measurements show that no change has occurred in the total quantity of serum albumin. In the absence of direct blood-volume measurement, changes in the red-cell count or hemoglobin may be useful in interpreting sudden changes in plasma volume. The determination of the albumin-globulin ratio may also be helpful in deciding whether a significant change in serum albumin has occurred.

To maintain nitrogen balance and to attempt to increase the serum albumin level one might consider the use of one or more of the following nitrogen-containing preparations: protein by mouth, amino acid by mouth, amino acid by vein, albumin intravenously, plasma intravenously and whole blood intravenously.

Adequate protein by mouth is of course indicated in all patients who are not nauseated or vomiting. Patients with renal insufficiency with normal blood-urea level may be given 2 to 3 gm. of

TABLE 8. *Some Advantages Pertaining to the Use of a High-Protein Diet in Patients with Renal Insufficiency associated with Edema without Azotemia or Acidosis.*

Improved nitrogen balance
Increased urea
Increased renal blood flow
Acid ash

protein per kilogram of body weight with advantage. In these patients a high-protein diet may be considered to be advantageous for several reasons (Table 8). Patients with elevated blood urea nitrogen will do better on a diet restricted to 0.5 to 1.0 gm. of protein per kilogram of body weight.

The oral administration of amino acid solution, a form of nitrogen that can be readily absorbed and that does not place so great a burden on the diges-

tive system as do the complex proteins, has been recommended for patients with renal insufficiency. Most patients, however, prefer complete proteins to the amino acid solutions that are available at present. Amino acid solutions by vein do not provide the colloid osmotic effect of protein solutions. Although amino acid solutions do form a ready source of nitrogen, and do represent complete replacement, there is little indication for their use in patients with renal insufficiency if albumin or plasma solutions are available. If parenteral therapy must provide all nutritional requirements for a period longer than one week, certainly the administration of amino acid solutions is indicated.

At present a solution of albumin has two advantages over a solution of concentrated plasma for patients with renal insufficiency: it can be prepared with a relatively low sodium chloride content, and it has a higher colloid osmotic pressure. Transfusions of whole blood provide hemoglobin in addition to plasma proteins and are the only effective treatment for the anemia so frequently associated with renal azotemia.

In the treatment of patients with azotemia without edema, it is generally recognized that forcing fluids is particularly advantageous in reducing the accumulation of metabolites in the blood. Many investigators believe that maximum glomerular filtration can be obtained if adequate quantities of water are ingested. Studies in dogs, however, reveal the fact that the rate of urine flow and the glomerular filtration (creatinine clearance) can be appreciably increased over the maximum obtained by fluid administration by mouth if glucose solution is administered intravenously. Further increases can be obtained if normal saline infusions are employed instead of glucose (Fig. 8). Until proved otherwise, it would appear to be advantageous to use these solutions parenterally in patients with azotemia without edema or impending cardiac failure.

Nausea and vomiting constitute a major complication in the treatment of patients with renal impairment. Under these circumstances all fluid and nourishment must be given parenterally (Table 9). It may be possible to administer water

TABLE 9. *Parenteral Therapy Required in the Presence of Nausea and Vomiting.*

Daily body needs.	
Water	2500 cc.
Calories	1200
Protein	25-50 gm.

by rectum; otherwise fluids and nourishment must be given intravenously or subcutaneously (Table 10). Under these circumstances one may attempt

to fulfill basic nutritional requirements by administering glucose and protein parenterally (Table 11). The provision of 1000 to 1200 calories and 25

dium and chloride, a decrease in the plasma volume and consequently dehydration and an increase in azotemia. Thus there is a real necessity for

FIGURE 8 The Effect of the Intravenous Administration of Glucose and Saline Solution on Glomerular Filtration in Normal Dogs

to 50 gm. of protein may be considered to meet minimum basic requirements under these circumstances. Vitamin preparations may be given parenterally. Because of the large quantity of glu

providing sodium chloride, in small quantities at least, during such periods of active diuresis

General considerations. The commoner disorders that occur in conjunction with renal insufficiency are summarized in Table 12. It is obvious that solutions containing sodium and chloride might prove advantageous in the treatment of the first group of disorders (nausea and vomiting, azotemia and dehydration), whereas saline solutions would be contraindicated in most cases in the second group (edema, hypertension and cardiac failure). It is also obvious that whereas a high-protein intake might be advantageous to patients

cose solution needed, water requirements are easily met. Glucose administration intravenously should not exceed a rate of 1 gm. per kilogram of body weight per hour for optimum utilization. Hypertonic glucose solutions and protein solutions should be given very slowly and in small quantities to patients with hypertension, cardiac enlargement or acute nephritis.

When fluids are forced, either by mouth or parenterally, in the treatment of patients with azotemia, it must be recognized that essential minerals, such as sodium and chloride, are also lost in excess. Continued treatment of this type may result in a striking fall in the serum level of so-

TABLE 11 Basic Nutritional Requirements

Minimum daily caloric requirement	1000
Calories from 50 gm. of protein (4×50)	200
Difference	1000
250 gm. of glucose is needed to provide 1000 calories. Therefore the administration of 2500 cc. of 10 per cent glucose solution will supply the necessary calories.	

with edema and hypoproteinemia, such a diet would be contraindicated in the presence of azotemia. Improvement can be expected in all cases, however, if glomerular filtration can be increased without placing too great a load on the heart. Disturbances as those observed in calcium

and phosphorus metabolism, creatinine and uric acid have not been discussed individually since, for the most part, they are corrected when glomerular filtration is improved. It is to be noted that no

reference has been made to the type of nephritis or renal insufficiency with which the metabolic disorder is associated. This has been purposeful since, with rare exceptions, treatment based on correcting the presenting metabolic disorders will not be altered by the type of underlying renal disease.

With these considerations in mind, one can now arrange a group of effective physiologic therapeutic agents for use in the treatment of the metabolic disorders associated with renal insufficiency (Table 13).

I believe that practically all that can be accomplished in correcting the metabolic disturbances that are associated with renal insufficiency can be accomplished by the use of these simple agents.

A diet containing the basic nutritional requirements for health

The problem is to match correctly the disturbances in function with the proper quantity of the indicated agent. Although the extent and progress of the underlying renal disease is the ultimate factor in prognosis, proper therapy may provide time for healing to take place in patients with an acute process, and may rehabilitate for months and even years an appreciable number of patients suffering from the effect of extensive and permanent impairment of renal function.

An outline of therapy suggested by the physiologic needs required to correct the metabolic disturbances that present themselves in patients with

renal disease follows. It is not to be presumed that these suggestions present all the effective forms of therapy or necessarily the most effective means of therapy; the outline is presented principally because it is based on physiologic considerations that should indicate appropriate measures.

Metabolic disturbances frequently associated with renal insufficiency. The treatment as outlined is based on the requirements of adolescents and adults. The same principles apply to the treatment of infants and small children, although quantitative requirements may differ appreciably and the administration of parenteral fluids will present greater practical difficulties.

GROUP I

1. *Edema.*

Purpose of treatment: Since in most cases edema is associated with hypoalbuminemia, therapy is directed toward increasing the colloid osmotic pressure of the serum, thereby increasing the plasma volume and aiding in the renal elimination of excess salt and water. A diet of acid-ash residue facilitates sodium loss and hence further reduces the quantity of extracellular fluid.

A. In absence of nausea and vomiting:

1. Diet, *salt free, high protein* (2-3 gm. per kilogram of body weight).
2. Fluids, 1500-2000 cc. by mouth daily.
3. Albumin,* 25 gm. intravenously daily. Plasma is less advantageous because of its high sodium chloride content. Ammonium chloride, mercurial diuretics, thyroid and urea may prove helpful but are not necessary if albumin is available for intravenous use.

B. In presence of nausea and vomiting:

1. Glucose solution, 1500-2000 cc. 10 per cent intravenously daily.
2. Protein (preferably albumin), 25-50 gm. intravenously daily.

The changes in body weight in a patient (P. B. B. H. M62053), a white man, 26 years of age, with a nephrotic syndrome of 3 years' duration, which followed the administration of albumin intravenously are presented in Figure 9. This patient had been bedridden for several months prior to the institution of albumin therapy and had failed to improve following treatment with a low-salt diet, high-protein intake, urea administration, occasional injections of mercurials and so forth, although on previous hospital admissions he had responded favorably to these therapeutic measures. It cannot be stated that albumin

*The human albumin used in this study was provided for experimental purposes through the courtesy of Dr. Edwin J. Cohn, Dr. Charles A. Janeway, Dr. Sam T. Gibson and Dr. Lorande M. Woodruff, of the Harvard Medical School. Albumin will not be available for general clinical use during the war because of the needs of the armed forces.

therapy intravenously was responsible for his improvement on this occasion. It can be stated, however, that this patient did present a marked albumin deficiency, and that parenteral administration of albumin solution was a sound method of compensating for the hypoproteinemia.

4. Venesection in presence of increased venous pressure.
5. Intravenous administration of fluids and protein solutions is *contraindicated*. Small

FIGURE 9. Changes in Weight in a Patient with the Nephrotic Syndrome.

2. Edema plus Hypertension.

Purpose of treatment. To increase the colloid osmotic pressure of the serum and at the same time to prevent overtaxing the heart.

- A. In absence of nausea and vomiting:
 1. Diet, salt free, high protein (2-3 gm. per kilogram of body weight).
 2. Fluids, 1500-2000 cc. by mouth daily.
 3. Albumin, 25 gm. in divided doses intravenously daily.
- B. In presence of nausea and vomiting:
 1. Glucose solution, 500 cc. 10 per cent intravenously every 6-8 hours.
 2. Protein (preferably albumin) 8 gm. intravenously every 6-8 hours.

3. Edema plus Hypertension plus Cardiac Failure.

Purpose of treatment. To improve the cardiac status and to facilitate the renal excretion of salt and water.

1. Diet, 1000-1500 cc. milk or fruit juice daily.
2. No additional fluids.
3. Digitalis and oxygen therapy.

quantities of hypertonic glucose solution—that is, 50 cc. of 20 per cent glucose—may be given on evidence of improvement in cardiac status.

4. Edema plus Acidosis.

Purpose of treatment. To increase the colloid osmotic pressure of the serum and to provide a relative excess of base.

- A. In absence of nausea and vomiting:
 1. Diet, 2000-3000 cc. milk daily, with added aluminum hydroxide, or an alkaline-ash diet of relatively high protein content.
 2. No additional fluids if milk diet is employed, otherwise fluids limited to 2000 cc. daily.
 3. Albumin, 25-50 gm. intravenously daily.
- B. In presence of nausea and vomiting:
 1. Glucose solution, 1500 cc. 10 per cent intravenously daily.
 2. Sodium lactate solution, 300 cc. 1/6 molar intravenously daily.
 3. Albumin, 25-50 gm. intravenously daily.

If sodium lactic is available in concentrated form (lactic acid U.S.P.), 4 cc. (equiva-

lent to 40 cc. 1/6 molar sodium lactate) can be added directly to the glucose solution to advantage, thereby decreasing the total volume of fluid.

5. *Edema plus Acidosis plus Azotemia.*

Purpose of treatment. To increase the colloid osmotic pressure of the serum, to increase glomerular filtration, and hence facilitate the excretion of sodium, chloride, water and end products of metabolism, and to provide a relative excess of base.

A. In absence of nausea and vomiting:

1. Diet, 2000-3000 cc. milk daily, with added aluminum hydroxide.
2. No additional fluids.
3. Protein (preferably albumin), 25 gm. intravenously daily for 3-7 days.
4. Glucose solution, 50 cc. 20 per cent intravenously for 3-7 days.
5. If satisfactory diuresis occurs and if edema disappears, give 300 cc. 0.85 per cent saline solution and 300 cc. 1/6 molar sodium lactate intravenously on every 3rd day that protein and glucose solution are given intravenously.

B. In presence of nausea and vomiting:

1. Protein (preferably albumin), 8 gm. every 8 hours.
2. Glucose solution, 750 cc. 10 per cent intravenously every 8 hours.
3. If edema disappears, give 300 cc. 0.85 per cent saline solution and 300 cc. 1/6 molar sodium lactate intravenously every 3rd day on the above regimen.

6. *Edema plus Acidosis plus Azotemia plus Hypertension.*

Purpose of treatment. To increase the colloid osmotic pressure of the serum, to increase glomerular filtration and at the same time to decrease azotemia, to provide a relative excess of base and to prevent overtaxing the heart.

A. In absence of nausea and vomiting:

1. Diet, 1500 cc. milk daily, with added aluminum hydroxide.
2. Glucose solution, 500 cc. 10 per cent intravenously once or twice daily. Albumin, 12 gm. intravenously once or twice daily.

B. In presence of nausea and vomiting:

1. Glucose solution, 2000 cc. 10 per cent intravenously in divided doses daily.

2. Sodium lactate solution, 300 cc. 1/6 molar intravenously in divided doses daily.
3. Albumin, 25 gm. intravenously in divided doses daily.

7. *Edema plus Acidosis plus Azotemia plus Hypertension plus Cardiac Failure.*

Purpose of treatment. To improve cardiac status and to provide a diet of low salt content, adequate protein, alkaline ash, adequate calories and minimum fluid.

1. Diet, 1000-1500 cc. milk daily, with added aluminum hydroxide.
2. No additional fluids.
3. Digitalis and oxygen therapy.
4. Venesection in presence of high venous pressure.
5. Administration of fluids and protein solution intravenously is *contraindicated*.

GROUP II

1. *Azotemia.*

Purpose of treatment. To increase glomerular filtration by providing an excess fluid intake; sodium chloride is given to increase plasma volume and to prevent salt depletion.

A. In absence of nausea and vomiting:

1. Diet with basic nutritional requirements.
2. Fluids, 3000-5000 cc. by mouth daily.
3. Glucose solution, 1000 cc. 5 per cent, or 500 cc. 10 per cent, intravenously once daily for 3-7 days.
4. Sodium chloride, 1-3 gm. (1 gm. enteric-coated tablets) daily in addition to usual salt in diet; after 1-2 weeks of observation it may be possible to increase the supplementary sodium chloride. Excessive gain in weight and development of edema are contraindications.

B. In presence of nausea and vomiting:

- Day 1. Glucose solution, 3000 cc. 10 per cent, and saline solution 1000 cc. 0.85 per cent, intravenously daily.
- Days 2 and 3. Glucose solution, 3000 cc. 10 per cent, and saline solution, 500 cc. 0.85 per cent, intravenously daily.
- Day 4. If nausea and vomiting are not corrected, intravenous protein (plasma or albumin) 25 gm. must be given daily, in addition to the above.

A patient (P. B. B. H. M63653), a white man, 53 years of age, had had a unilateral nephrectomy performed for tumor of the left kidney. At that time, a hydronephrosis

of the right kidney had been demonstrated. Immediately following removal of the left kidney, the patient did well. 4 months later he was readmitted to the hospital because of nausea, vomiting, weight loss and weakness. At this time he was noted to have rather marked azotemia, the blood urea nitrogen being 78 mg per 100 cc (Table 14). Urinalysis revealed a low specific gravity, but otherwise was not remarkable. Phenolsulfonphthalein excretion was 7 per cent in 2 hours. Additional sodium chloride and

chloride and sodium bicarbonate under these circumstances may be nothing less than miraculous, and one may expect to rehabilitate such a patient for a period of 2 to 4 years. Since patients with a requirement of sodium chloride as great as this are very unusual, it is much safer to begin with small doses, that is, 1 to 3 gm daily. In the absence of excessive weight gain, cardiac enlargement or edema the quantity of supplementary sodium chloride may be slowly increased. During this

TABLE 14 Laboratory Data on a Patient with Hydronephrosis

DATE	BLOOD UREA NITROGEN mg /100 cc	SERUM CHLORIDE m eq /l	SERUM CO ₂ COMBINING POWER vol /cent	BLOOD PRESSURE mm Hg	URINE VOLUME cc	TREATMENT
February 18	78	103	33	180/105	?	Forced fluid and glucose intravenously
22	67	7*	38	180/110	3500	As above
March 9	40	19*	34	190/105	2000-3000	Sodium chloride (2 gm) and sodium bicarbonate (1 gm) orally and glucose intravenously
April 7	2	114	53	115/110	2500	Sodium chloride (3 gm)

sodium bicarbonate were given on February 22 because the ingestion of large quantities of water by mouth and the administration of intravenous glucose in distilled water precipitated a striking reduction in serum chloride level. At present this patient is working full time and is being maintained on a daily diet that contains 50 to 60 gm of protein, 3000 to 4000 cc of fluids, 3 gm of sodium chloride and 3 gm of sodium bicarbonate.

2 Azotemia plus Acidosis

Purpose of treatment To increase glomerular filtration and to provide an excess of base.

A In absence of nausea and vomiting

- 1 Diet with basic nutritional requirements
- 2 Fluids, 3000-5000 cc by mouth daily
- 3 Glucose solution, 1000 cc 5 per cent, or 500 cc 10 per cent, intravenously once daily for 3-7 days
- 4 Sodium chloride, 1-3 gm by mouth daily in addition to usual salt in diet
- 5 Sodium bicarbonate, 3-6 gm daily by mouth, in presence of excessive weight gain or edema discontinue sodium chloride, if edema persists, reduce sodium bicarbonate

B In presence of nausea and vomiting

- Days 1, 2 and 3 Glucose solution, 3000 cc 10 per cent, saline solution, 500 cc 0.85 per cent, and sodium lactate, 500 cc 1/6 molar, intravenously daily
- Day 4 If nausea and vomiting are not corrected, intravenous protein, 25 gm daily, must be given in addition to the above

Occasionally one encounters a patient with renal insufficiency in whom the sodium and chloride losses are so great that 10 to 15 gm of sodium chloride must be given daily. Such a patient may present the signs and symptoms of adrenal insufficiency. Response to sodium

period of treatment patients should be under rigid observation. In the presence of hypertension supplementary sodium chloride must be administered with great care.

3 Azotemia plus Hypertension

Purpose of treatment To increase glomerular filtration and at the same time to prevent overtaxing the heart.

A In absence of nausea and vomiting

- 1 Diet with basic nutritional requirements
- 2 Fluids, 3000 cc by mouth daily
- 3 Intravenous glucose solution, 50 cc 20 per cent, intravenously once daily for 3-7 days
- 4 Sodium chloride, 1-3 gm by mouth daily in addition to the usual salt in diet. *In the presence of hypertension the quantity of supplementary sodium chloride must be followed very carefully.*

B In presence of nausea and vomiting

- Days 1 and 2 Glucose solution, 3000 cc 10 per cent, intravenously, to be given slowly and in divided doses of not more than 1000 cc every 8 hours
- Day 3 Glucose solution, 2500 cc 10 per cent, and saline solution, 500 cc 0.85 per cent, intravenously daily
- Day 4 If nausea and vomiting are not corrected, intravenous protein, 25 gm daily in divided doses, should be given in addition to the above on alternate days

4 Azotemia plus Acidosis plus Hypertension

Purpose of treatment To increase glomerular filtration, to provide an excess of base,

and at the same time to prevent over-taxing the heart.

A. In absence of nausea and vomiting:

1. Diet with basic nutritional requirements.
2. Fluids, 3000 cc. by mouth daily.
3. Intravenous glucose solution, 50 cc. 20 per cent, intravenously once daily for 3-7 days.
4. Sodium bicarbonate, 3-6 gm. by mouth daily.

B. In presence of nausea and vomiting:

Days 1, 2 and 3. Glucose solution, and 2500 cc. 10 per cent, and sodium lactate, 500 cc. 1/6 molar, intravenously, *slowly* and in divided doses of 1000 cc. total every 8 hours.

Day 4. If nausea and vomiting are not corrected, intravenous protein, 25 gm. daily *in divided doses*, should be given in addition to the above.

5. *Azotemia plus Hypoalbuminemia.*

Purpose of treatment: To increase glomerular filtration, to increase serum albumin level without increasing nonprotein nitrogen level, and to prevent edema formation.

A. In absence of nausea and vomiting:

1. Diet with basic nutritional requirements, which includes 1 gm. of protein per kilogram of body weight.
2. Fluids, 2500-3000 cc. by mouth daily.
3. Protein, 25 gm. intravenously daily for 3-7 days.
4. Glucose solution, 500 cc. 10 per cent intravenously daily for 3-7 days.
5. Supplementary sodium chloride, 1-3 gm. daily, on and after the 4th day; in the presence of hypoalbuminemia the quantity of supplementary sodium chloride must be followed very carefully.

B. In presence of nausea and vomiting:

Days 1 and 2. Glucose solution, 2500 cc. 10 per cent, and protein, 25 gm. intravenously daily.

Day 3. Glucose solution, 2500 cc. 10 per cent, protein, 25 gm., and saline solution 500 cc. 0.85 per cent, intravenously daily.

Repeat the programs of Days 1, 2 and 3 in order until nausea and vomiting disappear.

6. *Azotemia plus Hypoalbuminemia plus Edema*

Purpose of treatment. To prevent the fluid that are used to increase glomerular filtration from accumulating in the body.

A. In absence of nausea and vomiting:

1. Diet, *salt free*; otherwise includes all basic nutritional requirements.
2. Fluids, 2000 cc. daily by mouth.
3. Protein, 25 gm. intravenously daily for 3-7 days.
4. Glucose solution, 50 cc. 20 per cent intravenously daily for 3-7 days.
5. If satisfactory diuresis occurs and if edema disappears, give 300 cc. 0.85 per cent saline solution, intravenously on every 3rd day that protein and glucose are given intravenously.

B. In presence of nausea and vomiting:

1. Protein (preferably albumin), 8 gm. intravenously every 8 hours.
2. Glucose solution, 750 cc. 10 per cent intravenously every 8 hours.
3. If edema disappears, 300 cc. 0.85 per cent saline solution is to be given intravenously every 3rd day on the above regimen.

A patient (P. B. B. H. M63459), a white boy of 14 years of age, was admitted to the hospital on January 31, 1943, with signs and symptoms of acute nephritis. His clinical course during the first three weeks in the hospital was complicated by middle-ear infection and an attack of rubella. His blood urea nitrogen slowly increased to 163 mg. per 100 cc., and on February 19 he was drowsy, nauseated, azotemic, acidotic, edematous and unable to retain fluid or food. It was apparent that intravenous administration of dextrose alone was not helping him; sodium chloride intravenously was contraindicated because of his edema. It appeared that the best form of treatment that could be administered under these circumstances would be small doses of albumin, glucose and lactate solution given intravenously in the hope that some improvement in glomerular filtration might occur as the result of the increase in plasma volume. The albumin was given in divided doses—that is, 12 gm. administered very slowly—and the heart and circulation were watched very carefully. The striking improvement that followed is of great interest (Table 15). It cannot, of course, be attributed necessarily to the treatment. On this regimen, however, it was possible to provide the patient's protein and caloric requirement, and there is no doubt that this was of value in a boy who was undernourished. Of particular interest was the fact that the administration of protein intravenously in the presence of azotemia was followed by a positive nitrogen balance and a decrease in blood urea level (Fig. 10). Again, of special note was the striking decrease in serum chloride level that followed the continued administration of albumin, glucose and lactate solution intravenously and that necessitated the administration of sodium chloride on February 27

and 28 (3 gm daily for 2 days (Table 15). At present (May 25) this boy is up and about and is being maintained on a diet of 80 gm of protein daily. The blood urea nitrogen is less than 20 mg per 100 cc

7. Azotemia plus Hypoalbuminemia plus Edema plus Acidosis.

Purpose of treatment: To prevent the fluids that are used to increase glomerular filtration from

4. Glucose solution, 50 cc. 20 per cent, intravenously daily for 3-7 days.
5. If satisfactory diuresis occurs and if edema disappears, give 300 cc. 0.85 per cent saline solution and 300 cc 1/6 molar sodium lactate intravenously on every 3rd day that protein and glucose solution are given intravenously.

TABLE 15 Laboratory Data on a Patient with Glomerular Nephritis

accumulating in the body and at the same time to provide for an increased quantity of available base.

B In presence of nausea and vomiting:

1. Protein (preferably albumin), 8 gm intravenously every 8 hours.

FIGURE 10 The Effect of Protein Therapy on the Nitrogen Balance and Blood Urea Nitrogen Level in a Patient with Glomerular Nephritis

A. In absence of nausea and vomiting

1. Diet, 2000-3000 cc milk daily, with added aluminum hydroxide
2. No additional fluids
3. Protein, 25 gm. intravenously daily for 3-7 days

2. Glucose solution, 750 cc. 10 per cent intravenously every 8 hours
3. If edema disappears, give 300 cc 0.85 per cent saline solution and 300 cc 1/6 molar sodium lactate intravenously every 3rd day on the above regimen

Recently Luetscher and Blackman⁹ have described the development of a peculiar serum electrolyte disturbance in patients with uremia that followed sulfonamide administration. In most cases patients were admitted to the hospital in uremic stupor with a history of having had a respiratory infection treated for several days with sulfonamide medication. In the hospital, therapy consisted of large quantities of glucose and saline solutions administered parenterally. With the onset of diuresis, the serum sodium and chloride, which had previously been low, rose to unusual heights, that is, serum chloride 140 milliequiv. per liter and serum sodium 170 milliequiv. per liter. It appeared that the peculiar renal disturbance associated with sulfonamide administration permitted the excretion of water in excess of sodium chloride. If this disturbance could be detected early, the administration of large quantities of fluid by mouth and glucose solution by vein—*with no sodium chloride*—should be effective in rapidly reducing the abnormally high serum levels of sodium and chloride. It is obvious that such disturbances can rarely be detected without the aid of repeated serum chloride and carbon dioxide determinations.

SUMMARY AND CONCLUSIONS

Much of the confusion that now surrounds the treatment of renal insufficiency might be obviated by adopting a simple, straightforward plan of therapy based on a careful consideration of the agents required to correct the principal disturbances in body chemistry and physiology, rather than by adopting a plan of therapy that is dictated by the nature of the pathologic lesion in the kidney. Such an approach will necessitate familiarity with the chemical and physiologic changes that may be expected to occur in the presence of impaired renal function.

In the outline of a therapeutic regimen designed to improve or correct the metabolic disorders that are associated with renal insufficiency, *quantitative* as well as qualitative considerations require attention, since patients with kidney disease are unable to compensate adequately for either an excess or a deficiency of the indicated therapeutic agents. The therapeutic agents that

are required in the treatment of renal insufficiency are few and for the most part represent merely replacement of normal body constituents. Hypoalbuminemia is one of the most characteristic metabolic changes associated with renal insufficiency, and there is a great need for an unlimited supply of albumin for parenteral administration if patients with renal insufficiency are to be treated adequately. A plan of therapy has been suggested for use in the treatment of the commoner disorders associated with renal impairment. The successful application of such a program requires constant and intelligent day-to-day supervision. It also requires the availability of facilities for the determination of blood nonprotein nitrogen, serum chloride and carbon-dioxide combining power. Although the progress and extent of the underlying pathologic process in the kidney is the ultimate factor in prognosis, proper therapy may provide an opportunity for healing to take place in patients with an acute or active process, and may rehabilitate for months and even years an appreciable number of patients incapacitated by the effects of extensive and permanent impairment in renal function.

MENINGOCOCCAL MENINGITIS WITH PURULENT ARTHRITIS*

Report of a Case

JAMES P. CATELL, MD†

BOSTON

CASE REPORT

JOINT symptoms are not uncommonly associated with meningococcal meningitis and meningococcemia. Herrick and Parkhurst¹ refer to descriptions by the Massachusetts Medical Society as early as 1810, and Osler² notes an 1811 report of epidemic cerebrospinal fever by North in which "swelling like rheumatism in the joints" was described. Both papers give an excellent historical review of the subject.

No adequate statistical data on the incidence of such joint manifestations have appeared since the reviews of Herrick and Parkhurst¹ and Rolleston⁴ in 1919. In an analysis of 321 cases in an army camp, the former found a frequency of 4 to 7 per cent. Rolleston collected a series of 902 cases and noted an incidence of 65 per cent. The occurrence of purulent effusion necessitating aspiration is not well known. Among 502 cases of meningitis in the British Navy, Rolleston found 24 with arthritis but only 1 had sufficient fluid to necessitate aspiration. Herrick and Parkhurst¹ had 16 such cases out of 321 patients with meningitis.

Subsequent to these reviews, there is little more than an occasional case report of meningococcal arthritis until the appearance of a review of 23 cases by Schein⁶ in 1938. Fourteen of these are said to have had joint effusion, although the fluid was aspirated in only 6 cases. Hench, Bauer and their colleagues⁶⁻¹³ have published eight reviews covering the American and English literature of the past decade in a very thorough manner. The sections on meningococcal arthritis for the years 1939 and 1940 (the latest thus far published) report no purulent arthritis, and only a few cases were noted in the preceding years. Dingle et al.¹⁴ mentioned a case without effusion in 1941. Therefore, it may be justifiable to assume that meningococcal arthritis with purulent effusion is a rarity, and one would postulate that the incidence would be further diminished with sulfonamide therapy.

The case of meningitis with meningococcemia presented here is of interest because of the development of purulent arthritis after the institution of adequate sulfadiazine therapy.

A 52-year-old housewife (B C H 1050039) entered the hospital with chief complaints of confusion, joint pains and rash. She had been well until the evening of the 2nd day before admission. At that time she first complained of feeling chilly and displayed signs of mental confusion. The following day she noted generalized joint and muscle pains and a generalized red rash and developed a stiff neck. On the morning of admission she was further confused and was unable to recognize the members of her family, but did so following admission. The family and past histories were irrelevant.

Physical examination showed a well-developed and well-nourished white woman lying flat in bed in no acute distress when quiet, but crying out with pain on any motion whatsoever. The temperature was 101.2° F, the pulse 108, and the respirations 38. The patient was oriented as to time and place but sporadically confused concerning the details of her illness. Over her entire body there were petechiae that did not blanch on pressure and that varied in size from 1 to 4 mm in diameter, as well as petechiae of the bulbar conjunctivas and the buccal mucosa. There were also two 1-cm hemorrhagic blebs overlying a metacarpophalangeal joint on each hand. The tongue was coated, and the throat and conjunctivas were injected. The lungs were resonant to percussion and clear to auscultation. There was a slight enlargement of the heart to the left, the rhythm was regular, and there was a Grade 1 systolic murmur over the aortic area. Moderate voluntary spasm of the abdominal wall was noted, but rigors, localized spasm and tenderness were absent. The spleen and liver were not palpable.

The neck was extremely stiff. Brudzinksky's sign was present bilaterally but Kernig's sign was absent. The patient was lying with all joints of the extremities in semiflexion. Gentle, passive motion of fingers or fore arms elicited screaming but attempts to bring out Kernig's sign met with little complaint. There was no swelling, heat or redness of any of the joints. The physical and neurologic examinations were otherwise negative.

On lumbar puncture there was an initial pressure of 250 mm of water. Gray, turbid fluid was removed in which there were 12,450 white cells per cubic millimeter, with 98 per cent polymorphonuclear leukocytes containing gram-negative, intracellular diplococci. The total protein was 366 mg per 100 cc and the chlorides 663 mg. The blood sugar was too low to be read. Admission spinal fluid blood and throat cultures were found to contain Group 1 meningococci. Blood studies showed a hemoglobin of 82 per cent (Sahli), 4,760,000 red cells and 16,150 white cells 75 per cent of which were neutrophils. The nonprotein nitrogen was 24 mg per 100 cc. The urine was negative except for a + test for albumin. A blood Hinton test was negative.

Shortly after admission 5 gm of sulfadiazine was given by elixir and an oral dose of 1 gm every 4 hours. The

*From the First and Third (T-3) Medical Services, Boston City Hospital.

†Formerly house officer, Third Medical Service, Boston City Hospital.

temperature began to drop soon after admission and by midnight reached 97°F. (rectal), the blood pressure being 85/62 and the pulse rising at times to 150. The patient did not appear to be in marked collapse, although on one occasion she was sweating profusely and the skin was cool. She was given 30 mg. of calcium pantothenate intramuscularly, and desoxycorticosterone was made readily available, in the event of frank signs of the Waterhouse-Friderichsen syndrome. This state of relative hypothermia and hypotension persisted essentially unchanged until noon of the 3rd day, when the rectal temperature rose, reaching 100.8°F. that night, and the blood pressure returned to normal limits.

Although the blood level of free sulfadiazine was 15.6 mg. per 100 cc. the morning following admission, the blood culture was still positive at that time, but it was negative on all succeeding occasions.

The petechial rash disappeared completely by the 3rd day, at which time a maculopapular, blanchable, extensor-distributed rash appeared over the buttocks, knees, elbows, thighs and pretibial regions, but not on the back or abdomen. These lesions caused much distress because of marked pruritus, but had disappeared by the 7th day.

On the 6th day, the patient complained of leg pains in addition to the aforementioned arthralgia, and both knees were found to be hot, swollen, slightly red and exquisitely tender. The following day, turbid fluid, which clotted almost immediately, was aspirated from both knees. It contained 39,400 white cells per cubic millimeter, with 98 per cent polymorphonuclear leukocytes; no organisms were seen in stained smears, and the fluid was sterile on culture. The free sulfadiazine level of this fluid was 8.6 mg. per 100 cc. Concomitant with the development of the joint effusions there appeared a cluster of eight punctate, hemorrhagic, herpetiform papules on the volar surface of the right forearm. They were nonblanchable and caused no discomfort. These lesions faded slowly and there was only a residual erythema on the 23rd day.

Subsequent lumbar taps were done, all fluids being sterile and chemically and cytologically showing a return toward normal. The last was performed on the 7th day and clear fluid was withdrawn, which was normal in all respects except for 340 white cells per cubic millimeter, with 98 per cent lymphocytes. The knees were aspirated on the 8th, 11th and 14th days, and each time sterile fluid without detectable microscopic organisms was obtained, except for the last tap, when only 0.5 cc. of fluid was available and no studies were possible. The other two samples contained 26,200 and 78,700 white cells per cubic millimeter respectively, of which 99 per cent and 100 per cent were polymorphonuclear leukocytes. On the 11th day, with the patient fasting, joint aspiration and venepuncture were performed concomitantly. The fasting blood sugar was 81 mg. per 100 cc., but the joint-fluid sugar level was too low to be read. The blood protein was 4.86 gm. per 100 cc., and the nonprotein nitrogen 22 mg. The respective joint-fluid levels were 4.70 gm. and 24 mg. per 100 cc. These joints showed much improvement clinically between the 11th and 14th days, as evidenced by decreased pain, tenderness, swelling and limitation of motion.

The joints of the upper extremities had been decreasingly painful on motion, but on the 9th day swelling, tenderness and increased limitation of motion occurred in the left elbow. This joint was not tapped and the reaction subsided concomitantly with that of the knees,

though motion was somewhat limited for several days. Heat and passive motion as well as active motion and sporadic splinting were applied therapeutically to the effusive joints. This resulted in almost complete return of function on discharge.

Throughout the first half of the hospital stay, the temperature was of a mildly septic variety, although there was only one spike as high as 103°F. (rectal), and the pulse varied between 80 and 110. The white-cell count ranged from 15,000 to 24,550, and the blood level of free sulfadiazine ranged from 6.0 to 11.0 mg. per 100 cc. The drug was omitted on the 10th day and low-grade temperature continued during the subsequent week, although the joint reaction was obviously subsiding. Sulfadiazine was reinstituted in a daily dosage of 6 gm. on the 17th day and continued for 1 week. At that time the temperature had been flat for 48 hours and the drug was omitted. The temperature remained essentially normal until the time of discharge on the 29th day, and the white-cell count ranged from 9000 to 11,000.

Throughout the course, the patient was oriented as to time and place and variably somnolent, depressed, alert and euphoric. The lungs were persistently clear on physical examination and the cardiac murmur did not change. An electrocardiogram showed only sinoauricular tachycardia (rate, 107). Repeated x-ray films of the chest were negative. Roentgenograms of both knees and both elbows on the 18th day revealed no abnormalities except minimal hypertrophic changes of the left knee.

At the time of discharge, the patient was able to move about with facility and without pain, tenderness or stiffness of any joints except the left elbow. This joint was painless although it was limited to 15° of full extension.

The patient came to the hospital for follow-up examination 3 weeks after discharge and was able to extend the left forearm fully. The temperature was normal and the patient was asymptomatic except for generalized weakness.

DISCUSSION

The points worth considering in this case are the presence of a positive blood culture sixteen hours after institution of sulfadiazine therapy, the appearance of three somewhat different types of skin lesions during the course of the illness and the development of purulent joint effusions five days after an adequate sulfadiazine blood level had been obtained.

In general, the value of sulfonamides in the treatment of meningococcal infections is widely recognized.^{10, 11, 14-19} Rapid, dramatic and uneventful recoveries have been noted in cases of acute and chronic meningococcemia and meningitis with and without joint involvement. An exception to this rule is reported as having occurred in a patient with meningitis and meningococcemia who, ten days after sulfadiazine therapy was established, had persistently spiking fever and purulent effusion into a knee joint.¹⁵ He had had no joint swelling on admission. The fluid was sterile on aspiration and the temperature and joint symp-

toms subsided gradually. The patient was essentially well three weeks after admission and was discharged.

The positive blood culture in the present case, in view of the blood level of free sulfadiazine (15.6 mg. per 100 cc.), is not consistent with published clinical observations. This fact was commented on by Dr. Maxwell Finland, who saw the patient in consultation. This finding suggests, perhaps, a relatively refractory strain of meningococcus. Such a phenomenon would explain the elevated temperature until somewhat late in the course of the illness, and the development of a septic focus not evident at the time of admission.

The rash noted on admission was petechial and typical of meningococcal septicemia. The second rash, a maculopapular, blanchable, extensor-distributed lesion appearing on the fourth hospital day, is characteristic of sulfonamide toxicity.²⁰⁻²³ It is also described by Herrick,²¹ in association with joint effusion, as characteristic of meningococcal infection. Stott and Copeman¹⁰ note that there may be such a rash with or without a central, hemorrhagic area in chronic meningococcemia. This eruption was fading on the sixth hospital day, when the evidence of frank knee-joint effusion was first noted. However, the earliest clinical evidence of joint effusion may have been missed, since the polyarthralgia of admission was still present. The appearance of the third rash on the sixth day, a localized collection of eight punctate, herpetiform, hemorrhagic, lesions 2 mm. in diameter on the volar surface of the right forearm, was possibly associated with a sporadic bacteremia. The source of such a bacteremia could not be determined but might have been in the knees, although knee and blood cultures at that time were sterile.

In 1919, Herrick and Parkhurst¹ categorized the various joint phenomena associated with meningitic infection, and their classification has been generally adopted with few modifications.^{5, 7, 9, 25} Briefly, they suggest three groups. In *Type A* an acute polyarthritis appears as an initial or early symptom, coincident with the petechial rash, and is usually transitory. There is marked pain and tenderness on motion but little or no effusion, and the symptoms are attributed to hemorrhagic lesions of the joints and synovial structures. This type may be present or absent in a given case and may run into the second form, *Type B*. This usually occurs about the fifth day of the disease. It is usually monoarthritic, affecting a knee most commonly, and is characterized by signs of purulent effusion. The aspirated fluid is mucinous, purulent, hemorrhagic or any combination of these; it contains 1000 to innumerable leukocytes per cubic

millimeter, and meningococci are found by smear or culture or both in about one third of the cases. There is less spasm, pain and tenderness than one would expect from the appearance of the joint, and the signs usually last one to four weeks, with subsequent complete recovery. *Type C* refers to joint involvement associated with serum therapy, a type which is of little concern here. In a series of 321 cases of meningitis, Herrick and Parkhurst found 14 *Type A* and 16 *Type B* cases, although a review of the brief case reports they give leaves one in some doubt as to their rigidity in applying the criteria they set up. Autopsy data are not available on the cases that failed to recover.

Keefer, Parker and Myers²⁵ have described the gross and microscopic pathology of knee joints in 2 patients with meningococcal arthritis. The first patient, with a proved case of meningococcal meningitis, developed pain, tenderness and slight swelling of the left elbow on the thirteenth day of illness and died on the twenty-first day. The knees were opened for post-mortem examination, although the patient had never shown signs or symptoms of knee involvement. No evidence was found of bone or cartilage destruction, and there was an intact synovial surface layer. The deeper layers of the synovia, however, showed an acute inflammatory reaction and numerous gram-negative diplococci, mostly extracellular. In the second case, a patient with proved meningococcal meningitis, there was pain in both knees, and death on the third day of the disease. At autopsy, there was no excess of synovial fluid in the knee joints and the microscopic picture noted above was observed. However, in addition the surface layer of synovial cells was swollen, necrotic or entirely absent in some places, leaving a surface of granulation tissue and a thick layer of cellular exudate composed of polymorphonuclear leukocytes. There was no extension deep into the capsular tissue. In summary Keefer et al., note: "Meningococcal arthritis is a metastatic lesion involving first the deeper synovial tissues. Later, infection invades the superficial cells with effusion of fluid into the joint cavity and varying degrees of destruction of the cartilage. It is essentially a metastatic acute synovitis." If these tenets are correct, the criteria of Herrick and Parkhurst¹ of *Type A* as an early transitory, hemorrhagic polyarthritis and of *Type B* as a later, protracted monoarticular synovitis are incorrect and the typing is superfluous. However, more clinical data correlated with pathological findings are necessary before the classification can be justifiably dismissed. Herrick and Parkhurst's observation of exquisite tenderness of *Type A* joints and relatively few subjective signs in the

Type B group is not consistent with the pathology reported by Kcefer et al. The present case demonstrates no sharp line of demarcation between nonexudative and exudative arthropathy, and in the latter type of involvement the joints were very painful and quite consistent with their clinical appearance.

Comparable symptomatology in swollen joints is reported by Schein.⁵ He reviewed 23 cases of meningococcal infection with articular involvement, devoting emphasis to the generally good prognosis that Herrick and Parkhurst gave to such joints. Contrary to this, Schein found that many patients needed orthopedic treatment and 3 patients developed ankylosis. However, at least one of these, judging from the case descriptions, had only some stiffness and no ankylosis. Brinton²⁶ states that pain and disability are uncommon in meningococcal arthritis and that the inflammation involves the synovial membrane and is not associated with changes of the bone ends. Keefer and Spink²⁷ report that gonococcal arthritis, which is closely related to the meningococcal form, may cause fibrous, but seldom bony, ankylosis. The greater the amount of fluid that collects in the joint space, the less the chance of destruction, according to these authors. Therefore, large joints like the knee have a relatively better prognosis. The case reported in this paper bears out this thesis in that there was residual stiffness in the elbow for some time after the knees were functionally normal. There were essentially no joint symptoms three weeks after discharge.

In view of the inability to culture organisms from aspirated joint fluid on three different occasions, the pyrexia and the maculopapular rash, it was suggested that the symptoms might have been due to sulfadiazine toxicity. The literature referring to sulfatoxic arthritis is not extensive. Hench, Bauer et al.,¹⁰⁻¹³ Keefer,²² Finland et al.²⁰ and Spink and Hansen²³ in reviews of toxic manifestations of sulfonamides either mention transient arthralgias or do not include a section on joint symptoms. However, Long et al.²⁸ in such a review state: "Painful joints have been reported in the course of sulfanilamide therapy and we have noted several patients who have received sulfathiazole have had exquisitely tender, swollen joints. . . . [This] may be puzzling in gonorrhea because of the resemblance to gonorrheal arthritis." This paper has no bibliography. The only case of true joint effusion attributable to sulfonamide toxicity is that of Glicklich and Sherman,²¹ in which a patient developed effusion of both knee joints during sulfadiazine therapy. Fifty cubic centimeters of clear, serous, sterile fluid containing a few polymorphonuclear leukocytes was aspirat-

ed. The drug was omitted and the effusion subsided, but recurred when sulfadiazine was given again.

An attempt was made to differentiate sulfatoxic arthritis and meningococcal arthritis in the present case on the basis of cytology and chemistry of the aspirated synovial fluid. A number of informative studies on the clinical physiology and pathology of synovial fluid have been made by Ropes et al.,²⁹ Keefer et al.,^{27, 30} and Coggeshall et al.³¹ Judging by these reports, the fluid in the case presented here was definitely abnormal, having a high count of leukocytes, almost exclusively polymorphonuclear. According to Coggeshall,³¹ protein above 3.15 gm. per 100 cc., in synovial fluid is abnormal. Keefer and Spink²⁷ state that although a synovial-fluid sugar level markedly lower than the blood-sugar level in the fasting state does not necessarily mean an infected fluid, it is suggestive of one. The data on synovial fluid in the present case might obtain in any of a number of arthropathies but are most consistent with one of pyogenic etiology. However, no published material is available that enables one to state dogmatically that such findings could occur in sulfatoxic arthritis.

Therefore, although in a given case no definite etiologic conclusions can be drawn from the characteristics of joint fluid if it is sterile, it was believed on the basis of circumstantial evidence that the present case was one of meningococcal arthritis. After the sulfadiazine had been omitted for a week, it was reinstituted for seven days to rule out any possibility of sulfatoxic arthritis and there were no succeeding symptoms.

SUMMARY

A case of meningococcal meningitis with meningococcemia is presented, with the onset of purulent knee effusions six days after sulfadiazine therapy was begun.

The literature on the incidence, clinical types and pathology of meningococcal arthritis, as well as that of sulfatoxic arthritis, is briefly considered.

CLINICAL PROGRESS

CLINICAL CATALYTIC CHEMISTRY

WILLIAM T. SALTER, M.D.*

NLW HAVEN, CONNECTICUT

IT IS the purpose of this report to call attention to the development of a field of laboratory medicine that has been emerging from many diverse sources in the past decade. This field has to do with biological catalysts. A generation ago, Otto Folin, D. D. Van Slyke, S. R. Benedict and others initiated a feverish study of metabolites that culminated in modern clinical chemistry. The metabolites studied—for example the blood sugar—are usually present in concentrations that may be described in milligrams of blood or tissue. Likewise, the daily excretions thereof are frequently measurable in grams or in sizable fractions of a gram-molecule. On the other hand, in recent years clinical studies have shifted more and more toward the description of specific catalysts, the concentrations and excretions of which are described in micrograms. This thousandfold change in parameters is the logical corollary of the nature of catalysts, in that biologic catalysts expedite the turnover of relatively large amounts of metabolite without contributing to the final product. For this reason, although subject to loss through

wear and tear and leakage, a little catalyst goes a long way.

The clinical measurement of these catalysts has a special significance for two reasons. In the first place, much more specific information is obtained and therefore the clinical interpretation is the more certain. For example, the blood urea may be elevated under many diverse circumstances and the interpretation of a high blood urea nitrogen value requires an intimate knowledge of the patient and his history. On the other hand, although an intimate understanding of the patient is still essential, an elevation of the so called plasma "hormonal iodine" is prima-facie evidence of hyperthyroidism.

In the second place, because catalysts control the rate of metabolic turnover, their concentration has a peculiarly dynamic significance. For example, a single determination of the blood sugar records, at best, an equilibrium in carbohydrate metabolism under the conditions prevailing. In contrast, the height of the plasma hormonal iodine reflects directly the rate of dynamic metabolic turnover. In a sense, these catalytic levels are direct-reading speedometers that indicate at any given moment how fast certain specific physiologic systems are operating. For this reason, they tend

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III 6 8 pp Springfield Illinois Charles C Thomas Company 1942 \$5.00)

*Professor of pharmacology Yale University School of Medicine

more and more to replace the cumbersome functional or tolerance tests now in vogue.

Another advantage of this trend is that the technic employed is often catalytic in nature. Consequently the methods represent advances in two respects. First, they require much less material. For example, the hormonal iodine can be determined in 1 cc. of plasma instead of 10 cc. as required by the older titration method. Secondly, the methods have become more specific. Thus, by selecting the proper strain of yeast, the influence of thiamine on fermentation can be used to estimate the amount of thiamine in a sample of biological material.

These microcatalytic methods require more precise attention to the time of reaction than did many of the older stoichiometric methods. They frequently require micromanometric apparatus or direct-reading colorimeters like the Klett-Summerson.¹ They demand also scrupulous attention to thermostatic control, because the rate of most biochemical reactions is significantly influenced by temperature. In general, these methods have been applied to the following types of substance: Hormones, vitamins, enzymes and electrolytes, including the hydrogen ion. The following examples illustrate some applications and certain precautions peculiar to these procedures.

HORMONES

In the case of hormones, two recent developments are of special interest, namely the application of iodide catalysis to the determination of plasma hormonal iodine, and the development of a new photometric technic for determining androgens and related 17-ketosteroids.

Determination of plasma hormonal iodine. This method is the outcome of physicochemical experiments by Sandell and Kolthoff² on the rate of reduction of ceric ions by arsenious acid. In its simplest terms the reaction may be expressed thus: (Yellow) $Ce^{+++} \rightarrow Ce^{++}$ (Colorless)

This reaction is markedly accelerated by iodide ions. Kolthoff and his co-workers studied the various conditions involved, including the concentration of total electrolyte and the temperature. Subsequently Chaney³ proposed adapting the method to the blood iodine.

Before the plasma is analyzed for iodine, it should be partitioned to separate the protein-bound from the inorganic iodine, as described by Salter.⁴ In this way, even accidental contamination with iodine during sampling or subsequent handling may be successfully eliminated. This treatment is conveniently carried out in graduated centrifuge tubes (15-cc. capacity). The reagents may be either

those of Bassett, Coons and Salter⁵ or those of Man, Gildea and Smirnow.⁶

This method is still subject to improvement, particularly with regard to the preliminary precipitation, ashing and other manipulation of the plasma. Nevertheless, the data obtained in this laboratory on the final determination (Table 1) illustrate its dependability and usefulness. In other words,

TABLE 1. *Determination of Plasma Hormonal Iodine.*

FUNCTIONAL RANGE	EQUIVALENT PLASMA CONCENTRATION (P) microgm./100 cc.	TIME FOR REACTION (T) min.	CONSTANT (P X T)
Myxedema	1	17	20
		22	
	2	9	20

	10	2.2	22
	12	1.7	20
	14	1.4	20

under standard conditions, the amount of iodine in the aliquot is inversely proportional to the time observed. The value of the constant, of course, depends on the temperature adopted for the procedure and other factors that must be controlled. It should be noted that the normal amount of iodine in 1 cc. of plasma is 0.00000005 gm.

This method, as it is improved, is undoubtedly destined to extensive clinical use. Plasma can even be mailed to laboratories, packaged like Wassermann samples, over considerable distances. Because a single determination of basal metabolic rate is notoriously unreliable, and because Salter, Bassett and Sappington⁷ found the plasma hormonal iodine to be a more reliable clinical diagnostic procedure than determination of the basal metabolic rate, this method will ultimately prove important.

Determination of 17-ketosteroids. Pincus's⁸ reaction is likewise in use in this laboratory, and is presenting advantages over the Zimmerman type of reaction,⁹ employing meta-dinitrobenzene. The latter reagent, unfortunately, reacts with urinary pigments or chromogens to yield false colors that confuse the final determination. Various attempts to correct for this large and variable blank have not proved satisfactory.¹⁰ The values in Table 2,

however, obtained by Dr Raymond Cahen in this laboratory, indicate that the Pincus reagent (an timony trichloride) may be incorporated in a simplified urinary ketosteroid technic that will facilitate widespread clinical studies of androgen excretion. The colors developed by this reagent are

in the blue-green and yellow-green range, instead of the yellow-red range of the Zimmerman reaction.

It will also be observed that the general range of values given by this reagent is lower than that of the Zimmerman reaction. Furthermore, there are qualitative differences between the two reactions in that they do not measure the same ketosteroid configurations. Some of these qualitative differences may be summarized. After heating with antimony trichloride and dilution with glacial acetic acid, an intense blue color (absorption maximum at 610 m μ) is developed by androstene and its isomers and by androstene-17. Dehydroandrostene and pregnadiol show weak, yellow blue colors. The shade of color varies with the diluent. Thus, in chloroform, androstene shows absorption maxima at 560 and 620 m μ .

Quantitatively, the chief difference from the Zimmerman reaction shown by neutral extracts of urine occurs in the nonalcoholic ketonic fractions. As shown by Table 2, there are also considerable differences in the beta-ketosteroid moiety. In general, however, these discrepancies do not obscure the interpretation of the results in terms of the present concepts of ketosteroid metabolism.

In a previous article¹¹ discussed clinical vitamin determinations and pointed out that biologic methods were subject to several sources of error. Since that time, however, intensive work has been done in this field, especially with regard to the vitamin B complex. The field is too large to be reviewed in this article, and I shall therefore mention only the fermentometer method developed by Schultz, Atkin and Frey.¹² This procedure is based on the finding¹³ that the rate at which certain yeasts ferment glucose may be increased by

the addition of thiamine chloride. Although the original article describes apparatus of gross size, the procedure can readily be adapted to the micro-respirometer (Warburg) technic.

Previously, considerable inaccuracy was introduced by the presence in biologic materials of a substance or substances that, like thiamine, also speed up fermentation. This substance, called "PAYF" (pyrimidine accelerating yeast fermentation),¹⁴ may be closely related to or identical with 2-methyl-5-ethoxymethyl-6-aminopyrimidine. At any rate, Schultz, Atkin and Frey¹⁵ have largely eliminated this error by subjecting a second aliquot to the action of sodium sulfite, which destroys the thiamine. Thus the first sample gives thiamine plus PAYF and the second PAYF alone, which may be as large as 40 per cent of the total. By this difference between the samples, the thiamine is determined. The surprising accuracy of the procedure is illustrated by the series of assays in Table 3, performed in this laboratory by Dr. Rigby Roskelley. It must be confessed that this particular series is more consistently accurate than many routine series, but it can be duplicated readily if special care is taken.

Although precautions must be taken to control the sample of yeast used, and to check each type of biologic material by known additions of thia-

mine examined simultaneously with the unknown, the method is far less irksome than the best chemical methods now available. Furthermore, for most purposes it is quite as accurate.

Suitable methods for other vitamins are now being worked out on the same principle, but they have not yet been so extensively tried as has the thiamine procedure.

HYDROGEN-ION CONCENTRATION

For years physicians and medical students have struggled with the distinction between hydrogen-ion activity (measured as pH) and alkali reserve

They have learned that a diminution in plasma bicarbonate often indicates acidosis—but not always. This traditional use of carbon dioxide as an index of hydrogen-ion activity in large part grew out of the technical fact that, formerly, direct measurement of plasma pH was extremely difficult. As a by-product of this indirect physicochemical approach to the measurement of hydrogen-ion activity, by means of the Henderson-Hasselbalch equation, a great deal of obscure thinking has flourished in clinics.

In a sense, this Gordian knot has been severed by the development of convenient methods for direct measurement of the acidity of the blood. The actual procedure requires only a few minutes, and only 1 or 2 cc. of blood. No great precaution is necessary against loss of carbon dioxide, beyond collecting the blood under mineral oil. A delay of even two or three hours is permissible before reading. The blood is treated with a suitable oxalate-fluoride mixture to prevent clotting and glycolysis.

The chief disadvantage of the method, which employs glass electrodes, is that the thermoionic amplifying devices required for the apparatus are expensive. They are, however, permanent, and in many laboratories much of the potentiometric equipment is already available.

Several types of apparatus have been described. One of the best procedures, however, is that of Nims.¹⁰ This method has the advantage that it measures the blood pH in terms of its deviation from that of a known buffer. In this way uncontrollable variations in the apparatus or environment are largely compensated.

If one wishes to construct the apparatus from general equipment, one of the better circuits is described by Nims. In addition to a good potentiometer, a thermoionic amplifier is necessary to activate a recording galvanometer, which is used as a nul-point instrument. Several excellent commercial instruments, however, are available in effectively compact form.

In making the determination, which requires only a few minutes, it is important that the blood and glass electrode be maintained at body temperature. This is essential because one is looking for rather small shifts in the activity of hydrogen ions and the temperature coefficient of the thermodynamic equilibrium involved is rather large. The electrode itself should be housed in a special water jacket, through which a stream of water circulates from a thermostatically controlled bath. It is convenient, also, to warm the tuberculin syringe from which the blood is delivered to the electrode. With special care, as little as 0.2 cc.

of blood may suffice for the final determination, but 1 to 2 cc. of whole blood is ordinarily used.

Formerly, extreme precautions were taken with fresh blood to prevent loss of carbon dioxide, and the glycolysis of glucose was neglected. It now appears that the formation of lactic acid from the blood sugar is the more important source of error. Accordingly, fluoride or some similar toxic agent is required.

The profound effect of changes in the hydrogen-ion concentration on rates of biologic reactions is so well known that it needs no further comment. Although its importance has been appreciated in clinics, the technical difficulties of measurement have caused greater emphasis to be placed on electrolyte patterns, which often have been misleading because they were incompletely determined. In any large clinic with an active laboratory service, there should no longer be any difficulty in deciding whether acidosis or alkalosis exists. If, however, one or the other abnormality in hydrogen-ion activity is found, it may still be desirable to determine the alkali reserve as a gauge of the severity of the disease and as an aid to therapy or prognosis. In my opinion, however, the problem of laboratory "diagnosis" can now be solved satisfactorily in a few minutes in any well-equipped clinic. Furthermore, the severity of the acidosis or alkalosis can be expressed quantitatively in terms of shift of pH.

ENZYMES

In a previous article¹⁷ referred to the clinical applications of the measurements of blood enzymes, for example acid phosphatase, alkaline phosphatase and amylase. To this list must now be added carbonic anhydrase. Physiologists interested in the rate of carbon dioxide transfer from blood to alveolar air have made many fundamental studies of this biologic catalyst. Among the most informative are those of Roughton and his associates.^{18, 19}

Recently at New Haven, Stevenson²⁰ has made an important clinical application in the study of the newborn. He finds that the concentration of circulating carbonic anhydrase is low in the newborn, and even lower in the premature infant. It is likely to be especially low in such infants as are cyanotic without obvious reason. The mortality rate in these cases is high, but post-mortem examination reveals little cause for death. Certainly, the older notion of congenital atelectasis—that is, failure of the fetal lung to expand at the first gasp—is fallacious in these cases. When, however, such infants are transfused, their blood enzyme becomes elevated rapidly and their cyanosis disappears. Furthermore, the mortality rate is considerably lowered. This striking clinical result

is a fascinating outcome of an abstruse study of chemical kinetics.

The enzyme concerned has been prepared in crystalline form by Scott and Fisher.²¹ Its action is to expedite the liberation of carbon dioxide from carbonic acid. Without its influence this gas cannot be unloaded from the blood at a speed commensurate with the rate of the pulmonary circulation. It is interesting that this delay indirectly impedes the uptake of oxygen, for which reason oxygen therapy is of no avail in the infants studied by Stevenson.

SUMMARY

A new field of clinical chemistry is arising that deals with biologic catalysts. The study of these substances involves specialized microtechnics, which are themselves often catalytic. Such measurements afford highly specific information concerning the functional effectiveness of definitive physiologic mechanisms. They also give momentary estimations of the dynamic rate at which such systems are operating.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Annual Meeting, May 24, 1943

THE annual meeting of the Council of the Massachusetts Medical Society was called to order at 7.00 p.m. in the Georgian Room of the Hotel Statler, Boston, on Monday, May 24, 1943, by the president, Dr. George Leonard Schadt, Hampden; 204 councilors were present (Appendix No. 1).

The Secretary presented the record of the stated meeting held February 3, 1943, as published in the *New England Journal of Medicine*, issue of March 18, 1943, and moved its approval. This motion was seconded and it was so ordered by vote of the Council.

Dr. Schadt, at this point, called the death of Dr. Charles S. Butler, treasurer of the Society, to the attention of the Council. He said his death took place on February 23, 1943, after a long illness and that the Massachusetts Medical Society had lost a great friend in his passing. He added that Dr. Butler had a gentle, sweet, kind character, that he was a gentleman of the old school

whose life exemplified what was in the poet's mind:

From first beginnings out to undiscovered ends,
There's nothing worth the toil of winning but laughter
and the love of friends.

He spoke of Dr. Butler's great devotion to duty, oftentimes at the expense of his health. At the request of the President, the Council stood in silence for two minutes in tribute to the memory of Dr. Butler.

Dr. Reginald Fitz, Suffolk, moved that the President appoint a committee to draw up suitable resolutions on the death of Dr. Butler. This motion was seconded by Dr. Walter G. Phippen, Essex South, and it was so ordered by vote of the Council.

Dr. Schadt appointed to the committee Dr. William H. Robey, Dr. David Cheever and Dr. Reginald Fitz.

Dr. Harold R. Kurth, Essex North, was recognized. He read a statement (Appendix No. 2)

which had already been published in the proceedings of the February 3, 1943, meeting. This matter was presented at this time as the result of a directive issued by the Council on February 3, 1943. It concerned a difference of opinion as to an individual's acceptability for membership in the Massachusetts Medical Society—the local committee on membership favoring the candidate and the state committee opposed. Dr. Kurth offered the following motion:

It is the sense of the meeting that the essential responsibility of whether or not graduates of unrecognized or foreign schools shall be admitted to the Society lies in the local membership committees, and that the central committee should concern itself essentially with the responsibility of seeing that no undue pressure has been brought to bear upon the local boards, either to endorse, or to bar, the approval of candidates.

This motion was seconded by Dr. Elmer S. Bagnall, Essex North, who said that he was one of three who examined the candidate in question. He added that in all the years he had been a member of the board of censors he had never seen a more adequate consideration to an applicant for admission to the Society than in this case. He disclaimed any intention of upsetting the by-laws. He said the motion had for its purpose an expression of opinion from the Council that the local committees have better opportunity to know those possessed of qualifications for membership in the Society.

Dr. Roy V. Baketel, Essex North, was recognized. He spoke as follows:

I have been a censor for quite a period of years. I should hate to tell you just how long. It has been longer perhaps than my memory; and I might say that at our meeting earlier in the month the officers in the district saw fit to give me five years more, so perhaps they do believe that I have tried to treat the applicant for membership in the Society in a reasonably honest, fairminded, square way.

Now I should like to say, in addition to the facts that have already been presented, because to me this is a rather strong fact in our failure to understand the decision handed down by the central committee, that we had, in November, two candidates, both graduates of a Grade C school, both men of foreign extraction, both practicing in Lawrence, both with the same type of recommendation. These recommendations came from men in long practice in Lawrence and its vicinity—men who had had contact with these applicants, men whose advice we believed in, men whose purpose we believed was honest.

The first of these applicants came from a below-standard school. He passed our examination very satisfactorily, and these recommendations, which were practically unanimous, were accepted by the central committee, and the man is today a member of the Massachusetts Medical Society. So far as we knew at

the time there was practically no difference—indeed, I am willing to state it a little more strongly—there was no difference in the qualifications of these men in our minds. Because of the fact that they came from subpar schools they were interrogated at the time more closely than might have been the case had they come from Grade A schools. And, further than that, we went into the factor of citizenship to a considerable extent. I know that we are all anxious in the light of the war to be sure that every man who is a member of this society, or a member of any American organization, is a patriotic citizen. We stood fast on those lines as to both of these men. The examination also included very specifically the ethics practiced by these men. We tried to obtain from them their belief in ethics, their attitude toward ethics, their attitude toward their fellowman in the daily pursuit of their practice, their attitude toward the patient under varying conditions; in fact, we tried to delve and did delve more deeply into their consciences than we have done with the average man from the average school.

We were certainly amazed when the report came back that one man was accepted and the other man was rejected. We believe that an injustice has been done. Certain correspondence took place between our secretary and the chairman of the general committee asking what the charge was, what we had left unsaid or undone, if they had information we did not have, and if they knew anything about this man that was against him in any way? We had no answer to that inquiry. We believed that they had no more information than we had, and I think they admitted it; therefore, it was all the harder for us to understand why one man should be accepted and the other man rejected.

As has been stated, we have no fault to find with the provisions of the by-laws. We think they are ample. We think their interpretation needs to be a little broader. We think they should be constructive; and we think, too, that in construing them considerations of a humanizing nature should apply when we pass upon applications of those whose circumstances may not be as fortunate as ours. We tried to assume such an attitude at that meeting, and not only did we want to be human to them but we wanted to be fair and square in every way. We still think these by-laws should not be changed but that interpretation of them should be along a broader basis and on more humanitarian lines.

Dr. George D. Henderson, Hampden, said that one might get the idea from the discussion that Dr. John P. Monks did not back up the central committee. This was a wrong impression. He expressed it as his own thought that all these candidates should be approved by the central committee. He added that he was opposed to the motion.

Dr. Fred H. Allen, Hampden, expressed a desire to know more of the facts before being called upon to vote on the question. He asked that some member of the central committee be asked to state that committee's point of view in this matter.

Dr. Harlan F. Newton, Suffolk, chairman of the Committee on Membership, responded. He said

that there was no question that the proper agent to examine candidates from substandard schools is the local committee. The approval of such committees, however, is often sent to the Committee on Membership without being accompanied with the reasons for such approval, and at times the Committee on Membership gets the feeling that the local committee, while it does approve the candidate, is not particularly keen about him. The question, he added, is simply this, Does the Council wish the local committees to have the entire say as to whether the candidate shall be passed along to the censors or does it want an intermediate check by the Committee on Membership, as at present provided for in the by laws?" Dr Newton pointed out that three supervising censors sit with the Committee on Membership and that, in spite of all this, mistakes may happen and may have happened in this particular case.

Dr Kurth disclaimed animus against the central committee. He added that local committees are in a favored position to probe the background and the ethics of candidates from substandard schools. Because of this it is difficult to understand why the central committee disapproves of a candidate already approved by a local committee.

Dr Arthur M. Jackson, Middlesex South, expressed the thought that the Council was wasting its time by voting something which attempted to upset the by laws.

Dr Curtis C. Tripp, Bristol South, moved that the whole matter be laid on the table. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORT OF EXECUTIVE COMMITTEE

The Secretary, in presenting the report (Appendix No 3), said the Executive Committee had now been in existence for two years. He added the circumstance which created this committee was indeed fortuitous inasmuch as it has enabled the Society to act promptly in matters pertaining to the war.

The committee, on the recommendation of the Committee on Membership, under the provisions of Chapter I, Section 5, of the by-laws, retired sixteen fellows, under the provisions of Chapter I, Section 7, allowed twelve fellows to resign, under the provisions of Chapter III, Section 3, allowed three fellows to change their membership from one district to another without changing their legal residence; under the provisions of Chapter I, Section 10, readmitted four fellows who had resigned while in good standing, readmitted two fellows who had been deprived of membership for nonpayment of dues, provided they discharged all

their obligations to the Society within one month; under the provisions of Chapter I, Section 6, remitted the dues, including those of 1943, of ten fellows, and under the provisions of Chapter I, Section 8, deprived fourteen fellows of membership for the nonpayment of dues.

The committee in conference with the Committee on Membership, under a directive of the Council given on February 3, 1943, recommended the following:

Fellows of the Massachusetts Medical Society shall not be required to pay further dues during their period of active service in the United States Army, Navy or Public Health Service. Those so requesting may receive the *New England Journal of Medicine* upon request and payment of the \$4.00 subscription fee.

The above does not apply to fellows going into active military service during the first year of fellowship in the Society.

The Secretary moved the adoption of the recommendation. This motion was seconded by a councilor.

Dr F. H. Allen asked why the Marines were left out. It was explained that the Marines had no distinct medical service, such being supplied by the Navy.

Dr Fitz, calling attention to the fact that there may be a few members of the Massachusetts Medical Society serving with the medical branch of the Canadian Army, offered an amendment to the recommendation so as to include the latter. This amendment was seconded by a councilor. The maker of the motion and its seconder having accepted the amendment, the chair declared it a part of the original motion. The recommendation was adopted by vote of the Council.

The committee reviewed the report of the Committee on Membership with regard to the establishment of a junior membership and approved of its recommendations.

The Council on February 3, 1943, referred to the Executive Committee four recommendations offered by the Auditing Committee of 1943. These recommendations are as follows:

That the investment of the Society's funds should be under the direction of a professional investment company.

That the report of the accountant should be more complete and include a list of investment transactions.

That the latter should include a statement that the report of the fiscal year is reconciled with the report of the preceding year.

That the duties of the Auditing Committee be turned over to a businessman trained as a bank examiner.

The Secretary said in connection with the first recommendation that the committee received from

the investment firm of Loomis-Sayles and Company an analysis of the Society's investment portfolio and certain advice with regard to a safe and profitable way in which this portfolio might be handled in the future. It was observed that there were too many items in the list, that the total yield was only 2.82 per cent and that the latter might be very materially increased without jeopardizing the principal. This firm would charge for handling the Society's investments 0.5 per cent on the first \$300,000 and 0.4 per cent on additional capital.

The Secretary read a letter addressed to Dr. Eliot Hubbard, Jr., by the New England Trust Company in which this bank explained its method of operation under four headings as follows:

To appraise and review quarterly the list of securities making up the account and to submit in writing the quarterly appraisals with recommendations for changes in investments that seem to be desirable.

To recommend changes of investments between quarterly reviews if desirable.

To confer with the treasurer at any time regarding the Society's investment problems.

To receive as compensation annually 0.2 per cent of the market value of the property in the account at the date of the original appraisal for the first year, and at the date of the anniversary appraisals for subsequent years.

The cost to the Society for handling the portfolio in this manner would be approximately \$420 per year.

The Secretary reported that the committee recommended the employment of investment counsel. He moved the adoption of this recommendation. This motion was seconded by a councilor.

The Secretary explained that the authority for the investment of the Society's funds rests, under the by-laws, in the hands of the Treasurer and that the Council at this time should do no more than say to the Treasurer, "We approve of you having at your disposal investment counsel—either that supplied by banks or that furnished by investment-counsel firms." The recommendation was adopted by vote of the Council.

With regard to the second recommendation of the Auditing Committee of 1943, the committee took notice of the fact that auditing committees are already provided with full authority, under the by-laws, to insist on the matters set forth in this recommendation and that, furthermore, it is the opinion of the committee that auditing committees should so insist.

The Secretary moved that the Council concur in these opinions. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The committee reported that it concurred in

the feeling of the Auditing Committee that the interval between the closure of the Treasurer's books and the stated meeting in February is too short to enable such a committee to do the kind of job which should be done. The Secretary announced that under new business amendments to the by-laws would be offered whereby the Treasurer's report and that of the Auditing Committee would be presented to the Council at the annual meeting instead of at the stated meeting in February.

The committee considered the recommendation made by the Committee to Aid the Boston Medical Library. This recommendation would have the Massachusetts Medical Society turn over to the Boston Medical Library the earnings of the Society's building fund. The committee expressed the opinion that a vote of the Council passed in June, 1929, makes this impossible. In connection with this subject, the committee offered two recommendations:

That the Massachusetts Medical Society acquire the space now occupied by the *Journal of Bone and Joint Surgery*.

That the Massachusetts Medical Society pay to the Boston Medical Library as rent a sum of money, up to \$6500 per annum, for its quarters thus enlarged.

The Secretary moved the adoption of the first recommendation. This motion was seconded by a councilor, and it was so ordered by vote of the Council. The Secretary moved the adoption of the second recommendation, and the motion was seconded. There was some discussion as to whether or not the word rent in the recommendation might involve the library in certain troubles anent its tax-free status. Dr. Edwin R. Leib, Worcester, asked if the legal side of the matter had been looked into. The Secretary replied that it had. Dr. David Cheever, Suffolk, confirmed this and said that it had been learned authoritatively that rent paid to a philanthropic, charitable or educational institution and used by that institution, for the purpose for which it exists under its charter, does not constitute rent in the sense of being taxable income. The recommendation was adopted by vote of the Council.

The committee reported that it had reviewed and approved the report of the Committee on Medical Defense and that of the Committee on Expert Testimony. The committee commended the report of the Committee on Public Relations to the attention of the Council.

The committee reported that the Army had approved of a plan to subscribe to the *New England Journal of Medicine*, placing a copy in every Army hospital of twenty-five beds or over. It

defeated a motion to send one hundred copies of the *Journal* to the Navy free.

The committee recommended that stated meetings of the Council begin at 10:00 a.m. and, while there is any business to transact, do not adjourn for lunch until 2:00 p.m. The Secretary moved the adoption of this recommendation. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The committee acknowledged the receipt of a communication from Dr. Charles F. Wilinsky et al., of the staff of the Beth Israel Hospital, including a protocol governing a plan for the care of the practices of such members of its staff as have entered or will enter the armed forces. The committee recommended that this matter be referred to the War Participation Committee and that this committee report to the Executive Committee at its next meeting. The Secretary moved the adoption of this recommendation. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The committee recommended that the Committee on Arrangements be instructed to provide for an exhibit and a luncheon meeting on anesthesia and for the suitable advertising of this meeting and exhibit in the program of the annual meeting. The Secretary moved the adoption of this recommendation. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The committee acknowledged the receipt of a letter from the National Conference on Medical Service, including a resolution which it was intended to offer at the meeting of the House of Delegates of the American Medical Association on June 7, 1943. This resolution called for the creation of a new committee of the American Medical Association made up of certain officers of that organization and so forth. This committee would maintain a Washington office and be supported by an appropriation from the American Medical Association of not less than fifty cents and not more than one dollar for every member of that organization. The committee recommended that this matter be referred to the Massachusetts delegation to the House of Delegates of the American Medical Association without prejudice. The Secretary moved the adoption of the recommendation. This motion was seconded by a councilor, and it was so ordered by a vote of the Council.

The committee reviewed a list of appointments made by the president-elect, Dr. Roger I. Lee, and approved of the same.

The Secretary moved the adoption of the Executive Committee's report as a whole. This mo-

tion was seconded by a councilor, and it was so ordered by vote of the Council.

REPORT OF COMMITTEES

Committee on Arrangements—Dr. Gordon M. Morrison, Middlesex South, chairman.

Dr. Morrison reported as follows:

We have no formal report to render. The annual meeting is our report. After having served on this committee one year I found myself precipitated into the chairmanship. Drs. Faxon, Halsted and Sturgis are all in the armed forces. During this last year Dr. Schadt, our president, Dr. Lee, our president-elect, and Dr. Tighe came to our meetings faithfully and helped us out a great deal. The committee that I have been fortunate enough to have work with me this year—Roy Heffernan, Richard I. Smith, Sidney Wiggin and Guy Bailey—could not have been a better committee for any chairman to have work with him. There is just one more person that I want to mention as having been indispensable to our committee last year, and that is our executive secretary, Mr. Robert Boyd. He has done an excellent job.

Dr. Morrison moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Publications—Dr. Richard M. Smith, Suffolk, chairman.

No report.

Committee on Membership—Dr. Harlan F. Newton, Suffolk, chairman.

Dr. Newton reported (Appendix No. 4) that his committee, while favoring in principle the establishment of a junior membership in the Massachusetts Medical Society, did not believe that this was the time to do it. He moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Finance—Dr. John Homans, Suffolk, chairman.

No report.

Committee on Ethics and Discipline—Dr. Ralph R. Stratton, Middlesex East, chairman.

The chairman reported as follows:

Your committee has held four meetings during the past year—at which thirty-four cases were discussed. These cases varied from requests for advice as to ethical procedure to complaints of member against member charging violation of the code. Several of these cases, which were involved in court procedures or might be so involved, were laid on the table pending legal action. All other cases were thoroughly investigated and decisions reached based on the data obtained. The most serious one—a charge of violation of Act III, Section 8, of the Code

of *Ethics* of the American Medical Association—was happily settled by an apology being rendered by the defendant to the injured fellow.

It is an interesting thought that throughout the year not one member has been asked to resign, or his name sent to the President for admonishment. All cases have been settled in committee and the decisions accepted by the fellows concerned.

At present there are before the committee two complaints of exorbitant charges against fellows, one case of improper advertising and three serious complaints of violation of the *Code of Ethics*. These are being thoroughly investigated and will be reported at a future meeting.

I cannot close this report without expressing the appreciation of his fellow committee members to Dr. William Brickley for his very kind gift of recent date, the pleasure of which we have sampled already.

Committee on Medical Education—Dr. Robert T. Monroe, Norfolk, chairman.

No report.

Committee on Public Health and Subcommittee on Public Education—Dr. Francis P. Denny, Norfolk, chairman.

In the absence of Dr. Denny, the Secretary read the report, which is as follows:

The series of broadcasts carried on by these committees with the title "Green Lights to Health" were discontinued in March, 1942.

This spring, at the instigation of the Massachusetts Department of Public Health, and with the offer of a favorable hour by Station WEEL, 4:30 to 4:45 p.m. on Wednesdays, the committee decided to arrange for a series of ten broadcasts. This series has been given the title "Health on the Home Front," and was started on April 7 and will end on June 9.

We are very grateful to the members of the Society who consented to give these broadcasts despite the many demands on their time.

The Secretary moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Medical Defense—Dr. Arthur W. Allen, Suffolk, chairman.

Dr. Edward D. Gardner, Bristol South, offered report, which is as follows:

At present, there are seven cases pending. During the past year, two cases have been disposed of—one, for lack of prosecution; the other, with a companion case, was nonsuited when it was reached for trial.

There have been two new cases entered during the past twelve months.

We wish to call attention again to the possibility of malpractice suits against fellows while in military service. We also urge that all men re-establish their insurance protection at the earliest possible moment and return to practice in case they have dropped their protection while on military duty.

Dr. Gardner moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Society Headquarters—Dr. William H. Robey, Suffolk, chairman.

No report.

Committee on Industrial Health—Dr. Dwight O'Hara, Middlesex South, chairman.

In the absence of Dr. O'Hara, the Secretary read the report, which is as follows:

At the last meeting of the Council the Committee on Industrial Health announced that it would hold another all-day meeting similar to that held at the Harvard Club last November. This was done, with an entirely new program, on April 24, 1943. One hundred and sixty registered, most of whom were present for the luncheon at noon, which was addressed by Dr. Alice Hamilton, and at which we were also honored by the presence of Dr. Robert H. Parry, health officer of Bristol, England, and by the presence of President Schadt.

The committee has continued to keep in touch with the State Department of Labor and Industries and with the State Department of Public Health, and has made a few fresh contacts with representatives of the Associated Industries of Massachusetts. The committee has advised several employers concerning medical services and has been able to aid in the placing of a few physicians in industrial medical work. It has met with a representative of the Council on Industrial Health of the American Medical Association, has prepared papers for publication in both medical and industrial journals, has delivered a broadcast on industrial health in co-operation with the Committee on Public Health, and has endeavored to be as active as possible on all fronts during this period of unprecedented industrial output.

The Secretary moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Massachusetts Committee on Procurement and Assignment—Dr. Reginald Fitz, Suffolk, chairman.

This report (Appendix No. 5) contained the following resolution:

WHEREAS, The War Manpower Commission has announced that there is immediate need for more physicians to serve as medical officers in the armed forces of the United States; and

WHEREAS, The War Manpower Commission has announced that Massachusetts should supply more medical officers than have so far been commissioned from the state; and

WHEREAS, A plan has been suggested by the War Manpower Commission through which the enrollment of medical officers may be accelerated with the help of county or district medical societies in certain states; therefore, be it

RESOLVED, That reviewing committees be established by each district society, the members of which shall be nominated by the district-society presidents and appointed by the president of the Massachusetts Medical Society. Such committees shall serve for the general purposes outlined in this report.

Dr. Fitz moved the adoption of the resolution. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Fitz moved the acceptance of the report as a whole. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Public Relations—Dr. Elmer S. Bagnall, Essex North, secretary.

Dr. Bagnall reported as follows:

The committee has conferred with the president of the Massachusetts Nurses Association and made some progress toward meeting and understanding mutual problems.

The Ellison subcommittee on relations with the Industrial Accident Board has made progress and has reason to believe the proposals made by us are being favorably considered by the board and the insurance carriers.

In this emergency we accept the obligation to initiate remedies to correct, so far as practicable, manifest deficiencies in the distribution of medical care by enlisting co-operation of all agencies concerned. Each district public relations committee should invite more intelligent co-operation of the public by whatever form of ethical propaganda best suits local needs. The doctor should exercise judgments based on the whole public interest when considering the request by his patient for hospital occupancy or for full-time special nursing. Serious nursing shortages exist in many communities. The district public-relations committee should stimulate formation of district nursing councils as outlined in a well-prepared prospectus concerning organization methods and component representation, which is procurable from Massachusetts State Nursing Association, 420 Boylston Street, Boston. Local telephone exchanges need better understanding of the problems involved in so-called versus real emergencies. We might attempt a practical definition of what is and what is not an emergency. Each district public-relations committee should move toward improvements in this field. The district public-relations committee should exert all reasonable efforts to prevent default of doctors in response to real emergencies even though our physical resources have been strained by the demands made upon them.

Dr. Bagnall moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Subcommittee on Tax-Supported Medical Care—Dr. Bagnall, chairman.

Dr. Bagnall reported as follows:

Because your chairman is able in his capacity as chairman of the Medical Advisory Board of the Department of Public Welfare to handle such problems

as are now arising in this field no meetings of the committee have been needed.

Policies had been agreed upon last year by the department and the Society. The department is endeavoring to extend these policies to local administration of the welfare medical care.

Dr. Bagnall moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Subcommittee Concerned with Postpayment Medical-Care Costs through Banks—Dr. Bagnall, chairman.

Dr. Bagnall reported as follows:

The Massachusetts Bankers Association has a committee co-operating with our committee to get a plan in operation in October. It is to supply the applications, note forms and so forth. The Massachusetts Medical Society is to endeavor to inform its members regarding the purpose and machinery of the plan. Suitable propaganda can be made available to the doctor by the Society for informing the patient about this means of budgeting for payment of the costs of medical care. All banks dealing with consumer credit will co-operate by taking up the notes and paying the doctor directly if the patient's credit justifies.

There are about 4600 active fellows in the society and it would cost about \$550.00 to inform the doctors and to provide them with machinery to utilize its facilities.

The Council, at the last annual meeting, authorized the institution of this project. We recommend that the president be authorized to add to the committee enough additional members to introduce the plan properly when the appropriation is approved by the Committee on Finance.

By way of additional information Dr. Bagnall pointed out that one year ago the Council adopted the principle of postpayment medical care as suggested by the National Shawmut Bank and authorized the Committee on Public Relations to proceed to put the plan into operation. Dr. Bagnall explained that this matter was not referred to the Committee on Public Relations or to the Executive Committee because of lack of time.

He moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Meet With the Medical Advisory Committee of the Industrial Accident Board—Dr. Daniel J. Ellison, Middlesex North, chairman.

No report.

Subcommittee on Prepayment Medical-Care Costs Insurance—Dr. James C. McCann, Worcester, chairman.

The report (Appendix No. 6) was presented by Dr. McCann.

Dr. Fitz moved its acceptance. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Legislation—Dr. Brainard F. Conley, Middlesex South, chairman.

This report, which was offered by the chairman, is as follows:

When the Great and General Court began its session for the year 1943, His Excellency, Governor Saltonstall, made the request, that because of the war, the Legislature complete its work within as short a time as possible. As a result of this request there appeared on the front page of every weekly issue of the Bulletin of Committee Work of the General Court, the following paragraph, to quote:

Because of the present wartime necessity to expedite legislative business, the time allowed for arguments may be limited at all committee hearings. It is therefore urged that all arguments be concisely stated, and that detailed or supplementary facts be submitted in writing. All information submitted will receive careful consideration. The co-operation of all interested parties in furthering this method will be most helpful.

Your committee wishes to report strict compliance in every respect with this pattern of procedure.

We also wish to report that this committee is very appreciative of the courteous and intelligent co-operation extended by the members of the joint Committee on Public Health of the Legislature.

The *New England Journal of Medicine* of May 13, 1943, contains a bulletin of as much committee work as had been acted upon up to the latest date possible of printing before this meeting of the Council. As soon as the present session of the Legislature closes, which will in all probability be within the next two weeks, all the bills of interest to the Society will have been acted upon and a completed list will be published in a similar manner.

In the report of this committee to the Council in the February meeting we acknowledged our cognizance of the anticipated decrease of income to the Society for this year. We have continued our careful watching of expenses and have endeavored to keep them down, in spite of the fact that the amount of work done was, little, if any, less than in previous years. We hereby submit for your information the following financial savings.

In order to reveal the amount of money saved, we must first of all call to your attention that the legislative committee spent, in round numbers, \$3900 during the last biennial session. Of this amount \$1500 was spent for legal counsel. This year this committee made an arrangement whereby we could get what we considered the best possible legal advice and pay for only what we needed. Therefore, we found that we needed only \$50 worth of legal advice. This advice has been received and paid for, and we have saved \$1450. That same year the amount of \$218 was paid to the Legislative Reporting Service. To date, and the session is about over, we have received all the help we needed from that source and at a cost of approximately \$70. Here is a saving of \$148. Copies of the *Who's Who in the Legislature* cost us \$45, just the same as two years ago. Travel expense, telephone, telegraph, clerical hire and incidental expenses

have amounted to slightly over \$50. In other words, this year your committee on legislation will have completed its work with a minimum of expense, namely, about \$220, as against \$3850 two years ago—a saving of \$3630.

Dr. Conley moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee to Examine WPA Records—Dr. Guy L. Richardson, Essex North, chairman.

Dr. Richardson reported as follows:

Work Projects Administration is at an end in Massachusetts. Since our last report to the Council we have not been called upon to adjust any differences between physicians and the WPA office.

The President of the United States has said that the WPA is entitled to an honorable discharge. Your committee requests its discharge, fearful it may be said of us as was said editorially of WPA itself. I quote: "We would go a little farther than the President. We would say, not only that the WPA is entitled to an honorable discharge, we would say it has been entitled to one for a long time."

Dr. Richardson moved the acceptance of the report and the discontinuance of the committee. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Cancer—Dr. Ernest L. Hunt, Worcester, chairman.

This report (Appendix No. 7) was offered by Dr. Hunt. It spoke of a meeting of the committee at which Mr. H. D. Fish, assistant managing director of the American Society for the Control of Cancer, Incorporated, presented a plan for popular education, in co-operation with the state program, which latter program has been backed by the experience and facilities of the Society. The committee thought that this plan was not expedient at this time. Dr. Herbert L. Lombard was present at this meeting and spoke of a two-day symposium on cancer that had taken place. This conference was held because it was realized that some type of cancer education should go on during the war. Out of it came a booklet, known as *Cancer: The what, whither, how*.

This report spoke of the improvement in the cancer situation in Massachusetts during 1942 in light of the report by Dr. Simmons on state-aided cancer clinics. It emphasized the fact that there must be no letup in the cancer-control effort because of the hardships imposed by the war.

The report concluded with the following statement: "It is our conviction that there is no substitute for the well-educated, experienced, conscientious doctor."

Dr. Hunt moved the adoption of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Postgraduate Instruction—Dr. Fitz, chairman.

No report.

Military Postgraduate Committee—Dr. W. Richard Ohler, Norfolk, chairman.

This report (Appendix No. 8) spoke of eleven exercises that were held at Fort Banks, ten at Camp Edwards, one at the Portsmouth Navy Yard and ten at Westover Field.

The committee expressed the view that this work had been very much worth while and that the officials of the Army and Navy felt likewise.

The committee offered the following recommendations:

That the committee be continued and directed to enlarge its activities as far as practical.

That an invitation be extended to the other New England state medical societies to co-operate in this project and that all medical officers of the Army and Navy in New England be offered postgraduate instruction in some form.

Further, that the Massachusetts Medical Society underwrite the expense of this effort.

Dr. Ohler moved the acceptance of the report and the adoption of the recommendations. This motion was seconded by a councilor.

Dr. Morrison asked how this postgraduate work fitted in with the postgraduate work of the federal government.

Dr. Ohler answered that he presumed that Dr. Morrison was referring to the plan announced in the *Journal of the American Medical Association*, issue of May 1, 1943. He added that this plan was under the auspices of the American Medical Association, the American College of Physicians and the American College of Surgeons and that it was still in the process of organization. He also said that in Boston, Philadelphia and Chicago such plans were already in operation and that it will be the policy of the committee controlling the plan, referred to by Dr. Morrison, to turn his work over to the groups which are already functioning.

The Secretary asked if he was correct in his understanding that the Military Postgraduate Committee was asking the Massachusetts Medical Society to underwrite the expenses incident to courses given in other states. Dr. Ohler answered in the affirmative, adding, however, that it was hoped that other societies in New England would ultimately share the expense. He said that the part of the Society, so far as it was related to other states, would be incidental only to getting the work started.

Dr. Carl Bearse, Norfolk, asked if it were not a bit dangerous to underwrite the project without knowing exactly how much money might be needed. Dr. Ohler expressed the thought that the \$500 would probably more than cover the expense.

Dr. Ohler amended his original report so as to add at the end of the third recommendation the words "in an amount not to exceed \$500." The seconder accepted this amendment. The motion as amended was adopted by vote of the Council.

Committee on Physical Therapy—Dr. Franklin P. Lowry, Middlesex South, chairman.

Dr. Lowry reported as follows:

This committee is primarily interested in research and education.

During the past year it can report nothing completed in research.

It has, however, sponsored a program of lectures in physical therapy for the medical personnel at Fort Devens.

Dr. Lowry moved the acceptance of the report. This motion was seconded, and it was so ordered by vote of the Council.

Committee on Expert Testimony—Dr. Frank R. Ober, Suffolk, chairman.

Dr. Ober reported as follows:

I thought that it was inadvisable to make a formal report, the reason being that there are fifty-three articles being published on forensic medicine under the editorship of Dr. Hubert W. Smith. Several of these articles have already appeared in the May number of the *Annals of Surgery*. A number are coming out in the *Yale Law Review*, the *Harvard Law Bulletin*, the *Rocky Mountain Bulletin* and the *Lippincott Clinics*. These are all being edited in book form. As soon as all the articles have been published in the magazines, they will be put in the hands of the members of the committee, and we shall then consider plans of procedure. It seemed very wise to wait until all this new material had been published before the committee commenced its study.

Dr. Ober moved the acceptance of the report. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Committee on Automobile Insurance Claims—Dr. Henry C. Marble, Suffolk, chairman.

No report.

Committee on Convalescent Care—Dr. T. Duckett Jones, Norfolk, chairman.

No report.

Committee to Study the Practice of Medicine by Unregistered Persons—Dr. Richard Dutton, Middlesex East, chairman.

No report.

Committee to Meet with the Massachusetts Hospital Association—Dr. Walter G. Phippen, Essex South, chairman.

No report.

Committee on Maternal Welfare—Dr. Judson A. Smith, Suffolk, chairman.

No report.

Committee on Rehabilitation—Dr. William E. Browne, Suffolk, chairman.

No report.

Committee to Aid the Boston Medical Library—Dr. William H. Robey, Suffolk, chairman.

No report.

Committee on Ways and Means to Conserve Physicians' Energies—Dr. Bagnall, chairman.

No report.

War Participation Committee—Dr. William B. Breed, Suffolk, chairman.

No report.

Committee on Nominations—The committee was composed as follows:

W. D. Kinney, Barnstable; P. J. Sullivan, Berkshire; W. H. Allen, Bristol North; E. F. Cody, Bristol South; G. L. Richardson, Essex North; Bernard Appel, Essex South; R. R. Stratton, Middlesex East; W. H. Sherman, Middlesex North; Dwight O'Hara, Middlesex South; D. D. Scannell, Norfolk; D. B. Reardon, Norfolk South; W. H. Pulsifer, Plymouth; W. B. Breed, Suffolk; W. F. Lynch (alternate), Worcester; and B. P. Sweeney, Worcester North (there were no representatives from the Franklin, Hampden and Hampshire districts).

Dr. Walter H. Pulsifer, Plymouth, reported for the committee as follows:

President: Dr. Roger I. Lee, Boston

Vice-president: Dr. Daniel B. Reardon, Quincy

President-elect: Dr. Elmer S. Bagnall, Groveland

Secretary: Dr. Michael A. Tighe, Lowell

Treasurer: Dr. Eliot Hubbard, Jr., Cambridge

Assistant treasurer: Dr. Norman A. Welch, West Roxbury

Orator: Dr. Joseph C. Aub, Boston

The President asked if there were any nominations from the floor. There being none, he requested the Secretary to cast one ballot bearing the names and designations of the above. The Secretary announced that he had complied with this request, whereupon the President declared, amid great applause, the election of the officers for 1943-1944 as above listed.

APPOINTMENT OF COMMITTEES

Dr. Roger I. Lee, president-elect, in announcing the list of committees for 1943-1944, said that the

personnel of these committees was for the most part the same as that of 1942-1943. He moved that the list, which had already been approved by the Executive Committee, be likewise approved by the Council without being read. This motion was seconded by a councilor, and it was so ordered by vote of the Council. (The list will be published with the proceedings of the Society in the July 22 issue of the *Journal*.)

NEW BUSINESS

At this point in the meeting Dr. Peirce H. Leavitt, vice-president, assumed the chair and Dr. George Leonard Schadt was recognized. He spoke as follows:

The subject I am going to discuss with you is something that has been in my mind all year long, but it seemed to me that I should wait until the annual meeting of the Council before bringing it out. I shall present the plan I have in mind and shall ask Dr. Roger Lee, the incoming president, to exercise his prerogatives in appointing a committee.

The last war, as you know, was a comparatively short war. Many of us had been in practice five, ten or fifteen years when we went away. I happened to be in service for twenty-two months; some of us were in for ten, twelve or fourteen months—I believe the average was fourteen months. We got back into practice quickly. Some of us were lucky and had little trouble, but a lot of the men had difficulty getting started. I know because I talked with a great many of them. They needed a car, or they needed an office.

I can think of the story of one man, named Bill Smith, who came back and was quite a hero. He had been wounded severely and was brought home, and when he came back he met John Jones, a banker, who thought Bill Smith was a wonderful hero and told him what a fine fellow he was. And then he said to Bill Smith, "What can I do for you?" Bill replied, "I should like to see if I can borrow a little money." The banker said, "Of course you can. I'll be glad to give it to you. How much do you want?" "Twelve hundred dollars." "By the way, what about collateral?" John Jones asked. Bill Smith said, "This will be only for a year." However, the banker looked at him with a cold eye and said, "If you haven't any collateral I can't let you borrow the money." That was poor Bill Smith's position. He was a great hero, he had fought for his country in the war and he had been wounded, but he never got the \$1200—at least not from the banker.

A lot of men came back wounded and could not go into the type of practice they had engaged in before. They would have liked very much to have gone into something like refraction, but they did not have the money and they could not do it. As the result of the war many men lost out, not because of their service, but because of the fact that they could not afford to rehabilitate themselves.

I think we have a great opportunity in the Massachusetts Medical Society today. This war is different. It is a long war. It has already lasted, so far

as we are concerned, nearly a year and a half. It is going to last another two or three anyway. Our friends have gone, men who have been in practice five, ten or fifteen years. Many of those men are coming back wounded or in ill health. A surgeon may never be able to operate again. An internist may never be able to do that type of work. If he could do refraction or skin work, if he could get started with six or ten months' headway, it would be a great thing for him. A great many coming back are going to need special treatment until their wounds and their nerves are healed, and a majority of them are coming back without collateral.

My plan—and I have talked it over with a few men in the Society—is one to develop a fund in the Massachusetts Medical Society. Call it the Postwar Rehabilitation Fund. Let it run something on the order of the Morris Plan, any member of the Society being able, without embarrassment and without collateral, to make application for a loan. That application is endorsed by one or two members of the Society. The amount would be limited, and each application would receive careful consideration. Such a scheme could be easily put into effect. To come to us rather than to an otherwise affable banker or to a loan shark would save our friends and our colleagues a tremendous amount of embarrassment.

I can see that all this needs a lot of study, and all that I am asking of you tonight is to appoint a committee for that purpose.

I can visualize a man coming home and wanting to go to Harvard or Boston University or Tufts for post-graduate study. Incidentally, possibly the medical school should cut the fee in half or cut it out entirely for the ex-service man. The amount of the borrowing might be \$1000 or \$1500. That can be decided. The time in which the loan has to be paid might run one or two years. That, too, would be decided by a committee.

I can visualize further. I can see men who are not coming back, who are leaving wives, and children who need to be educated. There are quite a number of paths this plan might follow.

You say, "Well, where are you going to get the money?" I think the preliminary fund could be obtained by assessing every member of the Massachusetts Medical Society who had not had the privilege of serving with the armed forces, because of age, disability or another reason, \$10, with the opportunity of contributing more if he so desired. I think we could easily get \$50,000 to start with, and if we needed more we have a backlog of over \$200,000. Why does the Massachusetts Medical Society need \$200,000 in bonds? That is something which has been a source of worry to me all year long. We have done nothing with it. It has just been invested. There must be something constructive we can do with the money instead of having it lie in our treasury.

Dr. Schadt moved that the incoming President, Dr. Roger I. Lee, appoint a committee of fifteen to study the desirability and feasibility of such a plan and to submit reports of progress at the October and February meetings of the Council and a

final report at the annual meeting in May, 1944. This motion was seconded by Dr. William B. Breed, and it was so ordered by vote of the Council.

Dr. Leavitt read the following obituary:

Dr. Hanford Carvell, a member of the Council from the Essex South District, died on February 15, 1943, at the age of sixty-seven.

Born in Marysville, New Brunswick, Dr. Carvell received his degree from the Baltimore Medical School in 1910. He was a member of the American Medical Association.

His widow, two daughters and a brother survive him.

Dr. Leavitt asked the councilors to stand in silence one minute in tribute to the memory of Dr. Carvell. The councilors complied with the request.

Dr. Schadt resumed the chair.

Dr. Donald Munro, Suffolk, moved that the following amendments to the by-laws of the Massachusetts Medical Society be adopted:

That Chapter IV, Section 4, of the by-laws of the Massachusetts Medical Society be amended by striking out the word "stated" and inserting the word "annual" and deletion of the words "in February."

That Chapter VI, Section 5, of the by-laws of the Massachusetts Medical Society be amended by striking out the word "February," as it appears at the top of page 21, and inserting in its place the word "annual."

This motion was seconded by a councilor

Dr. Munro explained that the purpose of these amendments was to allow the Auditing Committee sufficient time to do the job that it was supposed to do under the by-laws. The motion was adopted by vote of the Council.

The President announced that these amendments will be offered at the annual meeting of the Society in 1944 and that they will not be effective until favorably acted on by that body.

Dr. Munro moved the adoption of the following motion:

That the Committee on Publications be empowered to offer to the Navy Department 100 free one-year subscriptions to the *Journal*, to be distributed as the Navy may decide.

This motion was seconded by a councilor.

In connection with this motion, Dr. Munro said that he was offering it at the request of Dr. John Fallon, who was ill and consequently could not be present. He added that he personally favored the motion. He said that he had been informed by the editors of the *Journal* that the adoption of this motion would add but five cents to the cost of the *Journal* for each member per year. He em-

phasized how profitable this would be to the *Journal* from the standpoint of advertising.

Dr. Fitz asked if this had been discussed by the Executive Committee. Dr. Schadt replied in the affirmative and added that the committee had voted against it. Dr. Channing Frothingham, Suffolk, called upon the Council to reverse the action of the Executive Committee.

Dr. Richard M. Smith, Suffolk, favored the motion. He thought from a business point of view it was a good thing to do. He stressed the point that he was speaking as an individual and not as a representative of the Committee on Publications. Dr. Frank R. Ober favored the motion, as did Dr. William B. Breed, Dr. Peirce H. Leavitt and Dr. Donald Munro.

Dr. Carl Bearse, Norfolk, said that this matter had been given very careful consideration by the Executive Committee and that he thought the Council should back up this committee's stand.

Dr. Fitz moved that the motion be tabled and referred once more to the Executive Committee. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

The chair recognized Dr. James P. O'Hare, Suffolk. Dr. O'Hare read a letter from Mr. John M. Deely, district rationing officer, which is as follows:

Owing to the problems that have arisen in the administration of the food-rationing program, we find need of a board of advisors as relating to special diets certified by physicians.

We should deeply appreciate it if the Council of the Massachusetts Medical Society would appoint a committee to assist the state director of food rationing to furnish specific help in formulating a state-wide policy and to pass on doctor's certificates, and to serve as a review committee for unusual cases.

Dr. O'Hare said that many physicians have attempted to help their patients obtain more fuel oil and gasoline than is ordinarily allowed. The problem of food, he added, will be solved by a special federal committee that is now working on this subject. In the meantime the regional director needs help now to solve immediate and pressing problems. Dr. O'Hare moved that the President appoint a committee of three to assist, by advice, the regional rationing board in the problem relating to the special feeding of the sick. This motion was seconded by a councilor, and it was so ordered by vote of the Council.

Dr. Maurice Fremont-Smith, Suffolk, was recognized by the chair. He moved "that the President appoint a committee of whatever number he chooses to gather facts on this situation and make a recommendation to the Council." In of-

fering this motion Dr. Fremont-Smith spoke as follows:

Last year the by-laws of the Society were amended so that no foreign physicians coming to this country could get into the Society until after five years in this country. This is no time to go into any discussion. I think there are very good reasons for the Society having taken some action to protect its members against an influx of foreign physicians, many of whom were undesirable and many of whom did not know our methods of practice. On the other hand, there is a considerable body of men in the Society who believe that the Society has done itself no honor by putting this by-law on the book; in fact, we believe that the Society has opened itself to the criticism that it is looking after its own interests rather than those of the public welfare and that it is acting like a medical trust. I know this was not the intention of the Society. There are some arguments against this by-law—whether we should treat all men who come from Europe as one group. I think that that shows little confidence in our local selection boards and in our general election board. I shall not carry this any farther.

Dr. Fremont-Smith's motion was not seconded.

At this point Dr. Schadt introduced the newly elected officers amidst great applause. These officers responded briefly.

The President announced that on Tuesday morning, May 25, 1943, at 9:00 a.m., the scientific sessions of the one hundred and sixty-second annual meeting of the Massachusetts Medical Society would begin.

It was regularly moved and seconded that the Council adjourn. It was so ordered by vote of the Council at 12:00 m.

MICHAEL A. TIGHE, *Secretary*

APPENDIX NO 2

STATEMENT OF DR. HAROLD R. KURTZ

I wish to draw your attention to a matter which presented itself to the local membership committee of the Essex North District Medical Society. This matter arose in the course of the examination of one of its applicants for membership in the Massachusetts Medical Society just previous to the last censors' meeting. Having presented the facts in this case, I should like to call on the members of the Council for a sense of the meeting vote.

An applicant, who is a graduate of the University of Kansas City Medical School in 1932, licensed to practice medicine in Massachusetts in 1937, applied on July 17, 1942, for admission to the Massachusetts Medical Society. His application was sponsored by a reputable member of the profession in his community, and forwarded to the district secretary, together with six letters of recommendation from colleagues of high professional standing in this district. The Essex North local membership committee met, examined and interrogated the applicant very closely and, as a result of that examination and close interrogation, was of the unanimous opinion that he should be recommended for fellowship in the Society. I might state here and now that the local membership committee of Essex

North takes its work very seriously and investigates all applicants, particularly those of unapproved or foreign schools. Unless they meet its unqualified approval the committee does not hesitate to refuse their applications for membership in the Society. This has been amply demonstrated in the past by the number of applicants who have been refused fellowship in the Society.

The chairman of the central committee on membership was duly notified by the secretary that "it is the unanimous opinion of this committee, after due investigation, and close interrogation, that the applicant be recommended for fellowship in the Society." The local membership committee was somewhat surprised when it received word that the central committee on membership did not approve the application, in spite of the fact that it had been unanimously endorsed by the local committee. The reasons given by the chairman of the central committee were that his "educational qualifications were rather dubious." The local committee maintains that it already fully realized that situation, but felt, nevertheless, that it was in a better position to pass judgment on the man's qualifications for membership than was a group of men who in all probability did not know him at all. Furthermore, the local committee felt that his "educational qualifications" would be no different in two years than they were at the present time!

The second reason given by the central committee was "that the local committee was not particularly enthusiastic" and that "his recommending letters were not particularly informative." The local committee, in answer to this criticism, states that it feels that it is not necessary for the local committee to eulogize its applicants, and that when the local committee unanimously approves an applicant for fellowship in the Society, it means exactly that, and nothing else. The recommending letters of the applicant were honest expressions of opinions of physicians of high standing in his district, and due emphasis should be placed on these letters of recommendation.

The third criticism as stated by the chairman of the central committee was that it was of the "greatest importance" that the district membership committee should show "that the district society wants that applicant as a member." To this criticism the local committee replies that the Massachusetts Medical Society is representative of the highest standard of medical practice and medical ethics, and is the organization with which all physicians aspire to become identified. Therefore the applicant seeks the Society, and not the Society the applicant!

The purpose in presenting this matter to you is that it was felt by the Essex North local committee that it had spent a great deal of time in investigating this man's qualifications; it had spent almost an hour in interviewing this man and, as a result, had unanimously approved his application. Yet in spite of all this work, and in spite of the fact that this man was endorsed by a group of men for whom the local membership committee has the highest regard, his application was rejected by the central committee for the reasons which have been discussed above. It is felt

by the local committee that if the opinion of the local committees in general is to be upset by the central committee for such inadequate and unsubstantial reasons, that the function of the local committees will become purely superfluous in character. When Dr. John Monks, of the Suffolk District, introduced the change in the by-laws with reference to application for fellowship in the Massachusetts Medical Society, at the special meeting held on April 9, 1941, he stated, in speaking of the local committee, as follows:

The Committee on Medical Education and Medical Diplomas has sensed for a long time how helpless it was in obtaining adequate information on which to determine the desirability of candidates for fellowship; this point has already been discussed more fully in the formal report. It is believed that a local board will be in every way better fitted to obtain this information than the central committee. The number of men on the board is small, they are already in positions of responsibility in their local society, and two of the three are already members of the board of censors, which eventually will examine those candidates finally approved. Further, it is very definitely felt that in the case of graduates of unrecognized schools the essential responsibility of whether or not they should be admitted to membership in the local society should lie with their own nearby colleagues, not with those farther afield.

He furthermore stated, "The central committee shall take the responsibility of seeing that on the one hand undue pressure has not been brought to bear on the local board to recommend for approval an undesirable applicant, nor, on the other hand, that unwarranted local prejudice bar from approval a desirable applicant." It does seem, then, that the responsibility for recommending or turning down applicants for fellowship should rest with the local committee, under the supervision of the central committee. I might state furthermore, that this was the opinion in the minds of Dr. J. H. Blaisdell's by-laws committee in reviewing the mechanism for application for fellowship in the Society. It is the feeling of the local membership committee of Essex North that the principles, as expressed by Dr. Monks's and Dr. Blaisdell's committees, have been disregarded in this case, and that should this policy be continued, the important work of local committees will be jeopardized and must eventually become purely superfluous.

We have brought this matter to the attention of the Council because we are firmly convinced that the present by-laws for application for membership to the Massachusetts Medical Society are adequate and desirable. An applicant is tried, and approved by his colleagues, who are in an excellent position to know the type of professional ethics which this applicant practices far better than a group of men who in all probability know nothing of the applicant at all! It is hoped that the principles expressed by Dr. Monks will continue to dominate the endorsement of all new applicants to the Society.

APPENDIX NO 3

REPORT OF THE EXECUTIVE COMMITTEE TO THE ANNUAL MEETING OF THE COUNCIL

MAY 24, 1943

The Executive Committee of the Council has just finished the second year of its existence. During most of this time our country has been at war. When the enemy struck at Pearl Harbor, the committee had just about completed its organization. The echoes of this attack had scarcely died when in your name it pledged the skills and treasures of the Massachusetts Medical Society and, if necessary, the lives of its members to the President of the United States in what lay ahead. Pursuant to that pledge, our organization has been called on to make, almost overnight, many most important decisions. Fortuitous then was the circumstance which provided the machinery whereby this was made possible. The committee would have me say to you how greatly it appreciates this privilege of speaking in your name.

The Executive Committee on May 14, 1943, held a five hour session.

It acted, on the recommendation of the Committee on Membership, the following fellows as of January 1, 1943, under the provisions of Chapter I, Section 5, of the by laws.

E Stanley Abbot, Wayland
Alice H Bassett, Boston
William G Brooks, Boston
Charles C Carroll, Belmont
Frederick W Colburn, Hyde Park
Frank E Draper, Framingham
Joseph L Goodale, Ipswich
James J Goodwin, Clinton
Merton L Griswold, Uxbridge
Byam Hollings, Boston
William F Patterson, Medford
Warren D Ruston, Rockport
Charles J Smyser, New Wilmington, Pa
Frederick W Stuart, Dorchester
Edwin P Tripp, Falmouth
Ralph R Young, Jamaica Plain

It allowed the following fellows to resign as of January 1, 1943, under the provisions of Chapter I, Section 7, of the by laws.

Francis M Amaral, Point Loma, California
Joseph E Cinby, Hartford, Connecticut
Frances Cottingham, New York City
Mitchell Gratwick, Tarrytown, New York
S Harvard Kaufman, Pittsburgh, Pennsylvania
Nels A Nelson, Baltimore, Maryland
Purcell G Schube, Pasadena, California
Joseph C Stammers, New York City
Mary Frances Vastine, Philadelphia, Pennsylvania
William D Wheeler, Brookline
Lester R Whitaker, Augusta, Georgia
John C Whitehorn, Baltimore, Maryland

It allowed the following named fellows to change their membership from one district to another without change of legal residence under the provisions of Chapter III, Section 3, of the by laws.

Louis K Diamond, Brookline (Norfolk to Suffolk)
Francis D Ingraham, Brookline (Norfolk to Suffolk)
Joseph F Ross, Brookline (Norfolk to Suffolk)

It readmitted the following named fellows who had resigned while in good standing under the provisions of Chapter I, Section 10, of the by laws.

Attilio Canzanelli, Boston
Arthur H Crosbie, Boston
Henry L Hirsch, Springfield
Elie J La Liberte, Springfield

It readmitted the following named fellows, who had been deprived of membership for the nonpayment of dues, provided all their obligations to the Society are discharged within one month.

A Walter Cian, Boston
Patrick H Walsh, Fall River

It remitted the dues, including those of 1943, of the following named fellows who are ill and incapacitated, under the provisions of Chapter I, Section 6, of the by laws.

Franklin E Campbell, West Medford
Harry H Flagg, Charlestown
Edwards W Herman, Lincoln
Florence H Knowlton, Placencia, California
Bernard L Plouffe, Webster
Joseph A Ruel, Haverhill
Alpha R Sawyer, Chestnut Hill
R M Shukle, Boston
William J Sweeney Wakefield
Ruth Weissman, Jamaica Plain

It deprived of fellowship, for the nonpayment of dues, the following named fellows under the provisions of Chapter I, Section 8, of the by laws.

Gertrude W Baldwin, Boston
Chester P Brown, Swampscott
J Lawrence Campbell, Denver, Colorado
Italia M D Argenis, Worcester
Howard T Fiedler, Philadelphia, Pennsylvania
Grace E Gillis, North Haven, Connecticut
Max Ginsberg, Salem
Ruth K Jens, Brooklyn, New York
John J Kerrigan, Fall River
Morris A Silberg, Roxbury
Joseph A Smith, Athol
Elizabeth A Sullivan, Cambridge
Frederick C Warnshuis, Windsor, Ontario
Richard S Woodruff, Pittsfield

The committee, in conference with the Committee on Membership, under a directive of the Council given on February 3, 1943, reviewed the matter which had to do with the remission of dues of those members who had entered the United States Army, Navy or Public Health Service and offers the following recommendation.

Fellows of the Massachusetts Medical Society shall not be required to pay further dues during their period of active service in the U S Army, Navy or Public Health Service. Those so requesting may receive the *New England Journal of Medicine* upon request and payment of a \$4.00 subscription fee.

The above does not apply to fellows going into active military service during the first year of fellowship in the Society.

The committee reviewed the report of the Committee on Membership in regard to the matter of establishing a junior membership in the Massachusetts Medical Society.

and approves the report and its conclusions. This report will be offered by the Committee on Membership later in this meeting.

The Council referred, on February 3, 1943, to the Executive Committee four recommendations offered by the Auditing Committee of 1943:

That the investment of the Society's funds should be under the direction of a professional investment company.

That the report of the accountant should be more complete and include a list of investment transactions.

That the latter should include a statement that the report of the fiscal year is reconciled with the report of the preceding year.

That the duties of the Auditing Committee be turned over to a businessman trained as a bank examiner.

The officers of the Society, in connection with the first recommendation, engaged in certain preliminary conversations with Mr. R. H. Loomis, of the investment-counsel firm of Loomis-Sayles and Company, 140 Federal Street, Boston. The investment portfolio of the Massachusetts Medical Society was analyzed by Mr. Loomis, and a summary of this analysis is now presented.

Dr. Michael A. Tighe, Secretary
The Massachusetts Medical Society
8 Fenway
Boston, Massachusetts

Dear Dr. Tighe:

It was a pleasure to meet with you and your associates last month and go over the financial problems of the Massachusetts Medical Society. Since that time I have been given the opportunity of going over the present portfolio of the Society with the idea of noting possibilities of improvement of execution or any step that could be considered for better performance. I am advised that you are considering the employment of investment counsel for help in this matter. In going over the report I have had in mind what effect the employment of such counsel might have on the portfolio.

It would appear that Dr. Butler's administration was a very conservative one and succeeded in the main in maintaining dollar value. It is probable that during the particular period in which he operated this was, in the main, a proper objective, and personally I believe he did an exceedingly good job in a difficult period. To be sure he paid for it somewhat in increased work and in a very much reduced income. Nevertheless, his main objective was accomplished.

Without including the three or four purchases made a few weeks ago in the total tabulation, the account totals approximately \$228,000. There are eighty-one separate items averaging less than \$3000 each. It is easy to see how this was brought about when one considers the specific method used. However, I would say that there should be no need of so many items, particularly if one is going to deal exclusively in AAA securities. The accompanying ta-

ble gives an analysis of the securities in the portfolio by type of security:

	PRINCIPAL	PERCENT- AGE OF PRINCIPAL	INCOME	PERCENT- AGE YIELD
Cash:				
Savings banks.....	\$6,380	3.0	\$118	1.85
Other	20,464	9.0	-	-
Note (Boston Medical Library)	19,000	8.5	570	3.00
U. S. Government bonds:				
Short term	14,566	6.5	366	2.51
Medium term.	12,458	5.5	265	2.13
Long term	3,015	1.5	75	2.49
Short term bonds ..	36,244	15.5	997	2.75
Medium-term bonds..	31,943	14.0	1,352	4.24
Long-term bonds.....	46,317	20.0	1,671	3.61
Preferred stocks.....	3,450	1.5	143	4.15
Annuity policy.....	9,167	4.0	183	2.00
Demand loan	25,000	11.0	-	-
	<u>\$228,004</u>	<u>100.0</u>	<u>\$5,740</u>	<u>2.52</u>

You will note that the yield is 2.52 per cent. If you subtract the demand loan of \$25,000, which draws no income, the yield on the fund then would be only 2.82 per cent. This is an exceedingly low, in fact an unnecessarily low, rate of return. I would like to point out that if you should consider following these methods of investment it would be more sensible for you to invest the entire fund in three or four issues of Government bonds, which would average nearly as good a return as you are now getting. If you had only three or four Government issues they would require practically no attention and probably a much smaller safe deposit box. There would be scarcely any bookkeeping and practically no cutting of coupons. By raising the yield of the total fund to 4 per cent, which certainly is not an unduly high rate, you could very considerably increase the income return to the Society, and at the same time pay an investment-counsel fee. In other words, I can see an opportunity in this particular fund of, first, lessening the amount of work that your treasurer would have to do by cutting down the number of necessary issues and, secondly, of so increasing the yield on the fund as a whole as to provide greater income to the Society and at the same time pay an investment-counsel fee.

In advising you to seek a higher rate of return I do not want to convey the idea that I believe in subjecting the portfolio to undue risk. I believe that the fund as a whole should be conservatively managed and that, by all means, maintenance of principal should be your most important objective. In these days when inflationary factors are so rampant, I believe that your board should give consideration to the question as to whether or not you wish to any degree to try to protect your funds from a declining dollar value. In other words, it would appear that it might be highly desirable for you to attempt to maintain the purchasing power of the income of the fund. Thus far, in the operation of the fund this has not been attempted in the least, and perhaps it has been just as well that this policy has been maintained up to this time. On the other hand, it would appear that the element of inflation is strong enough to provide a proper basis for attempting in some small way at least to protect the funds against the ravages of inflation and a declining dollar.

From the above table you will note that 42½ per

cent of the total fund is in cash or short term funds. For maintenance of principal this may have been a proper proportion, but it has been paid for by an extremely low rate of return. It is questionable if the nature of your financial problems is such as to require such a large proportion of your funds in such near-cash securities.

I am not going to itemize the entire eighty-one issues because of the fact that they are so homogeneous in quality. They are all, with the exception of not more than half a dozen issues, of a very high grade as can easily be seen from a consideration of their prices and also from their yield. It is noticeable also in the list that there are a good many very high grade municipal bonds. These municipal bonds carry a tax free feature which is highly desirable to an individual having a high income and therefore, a high tax bracket. In view of the fact that your society, however, is not operated for profit you are not subjected to taxes in any case and, therefore, in purchasing municipal bonds you are buying something that you really do not need. Nevertheless you have to pay for it for the reason that such bonds are increased in price by the peculiar demand on the part of certain individuals. As indicated you have no such demand and, therefore, I would point out that such securities are really not suited to your purposes.

In operating this account it would be desirable to know what the nature of your budget expenditures are. It would be helpful to know what you consider essential as a checking balance for such expenditures.

Now in regard to our services that might be rendered to the Society. We would assign a competent consultant who would have charge of this account in the office and who would constantly be in touch with Dr. Hubbard in regard to any possible sales purchases or shifts in the account. The consultant would have available the entire work of our research department, consisting of approximately forty five people. The consultant would take the initiative in getting in touch with Dr. Hubbard although of course, Dr. Hubbard would have available at all times the opportunity of consulting directly with the consultant himself. Our research department has groups that are dealing with industrial securities, utilities, rail roads, bank and insurance stocks and municipals, and also it has men who are following the course of money rates, governmental expenditures and the course of industrial and agricultural prices. In recommending purchases and sales the consultant always gives reasons for the suggested action. It would be important for us to deal with one man and I understand that Dr. Hubbard has the necessary power to proceed. I speak of this particularly because I do not believe that we could be of as much assistance if it were essential to deal with a committee. We have had considerable experience along this line and we have always found that the results are clearly better if we can obtain action easily and quickly and this can usually only be done in dealing with one person. I mention this because upon it depends a great deal the success of any possible assistance we might give you. I am enclosing two copies of our usual contract. The fees which you will note on the bottom of the contract are as follows: annual fee, a rate of 0.5 per cent on the first \$300,000, with 0.4 per cent on additional capital.

Other questions concerning our services may occur to you. I shall be very glad indeed to answer any questions which may come up. In the case of the Massachusetts Medical Society, I feel certain that through the years the fund would be greatly benefited from the application of professional investment counsel. We would be very glad to serve you.

Thanking you for this opportunity, I am

Sincerely yours,
R. H. LOOMIS

The committee recommends the employment of an investment counsel. In offering this recommendation I am directed by the committee to make clear that it does not intend to commit the Society to just one type of investment counsel. The type supplied by banks should likewise be looked into.

The committee in connection with the second recommendation took notice of Chapter IV, Section 4, of the bylaws, which reads as follows:

The Council shall elect at the stated meeting in October, on nomination by the President or from the floor, the Auditing Committee, composed of two fellows who are not councilors.

This committee following the close of the fiscal year, shall require by a certified public accountant an examination of the assets and securities of the Society in the custody of the Treasurer, and of the Treasurer's books and accounts.

This committee shall verify the accountants examination and report its findings at the stated meeting of the Council in February.

It is the opinion of the committee that by this section, auditing committees are provided with full authority to insist on the matter set forth in this recommendation. It is furthermore the opinion of the committee that auditing committees should so insist.

In the debate which attended this subject, it was brought out by Dr. Eliot Hubbard, Jr., treasurer *pro tempore*, that usually the books of the Society could not be closed before January 20. Dr. Francis C. Hall, chairman of the Auditing Committee of 1943, emphasized the fact that this being so the time intervening between this date and the February meeting of the Council was too short to enable an auditing committee to do the right kind of job.

The committee with this in mind under the heading of new business, will offer such amendments to the bylaws as will provide that the Treasurer's and Auditing Committee's reports shall be offered to the Council at the annual meeting instead of the February meeting.

It was the judgment of the committee that the last two recommendations were covered by the action taken in regard to the first two.

The Council on February 3, 1943, referred to the Executive Committee a recommendation offered by the Committee to Aid the Boston Medical Library. This recommendation would have the Massachusetts Medical Society turn over to the Boston Medical Library the earnings of the Society's Building Fund. Under this directive the committee was ordered to give this matter the attention and study which it deserves and that its report be given at least twenty days before the annual meeting if it is possible to do so. The committee has complied with this order and its recommendations accompanied the call of this meeting. They are as follows:

That the Massachusetts Medical Society acquire the space now occupied by the *Journal of Bone and Joint Surgery*.

That the Massachusetts Medical Society pay to the Boston Medical Library as rent a sum of money, up to \$6500 per annum, for its quarters thus enlarged.

The committee in arriving at its conclusions in this matter took notice that the history of this organization contains many references as to the desirability of a permanent home. It noted that in 1928 a drive for funds for this purpose was conducted and that a sum of \$18,000 was realized. It noted also that in 1929 a joint drive for funds was conducted by the Boston Medical Library and the Massachusetts Medical Society and that the sum of \$180,000 was raised, one sixth of which, or \$30,000, was allocated to the Massachusetts Medical Society as its share.

In 1931 the Massachusetts Medical Society loaned, from this fund, to the Boston Medical Library \$24,703.29 from which it received 4½ per cent yearly up through 1939. The principal on this loan has been reduced, so that today it stands at \$19,000. In 1940 the interest rate was reduced to 3 per cent.

The Society's Building Fund as it stands as of December 31, 1942, is \$63,991.80—the sum of these original amounts raised plus their earnings over the years.

The committee, in its investigations, noted a vote which was passed by the Council in June, 1929, which reads as follows:

ARTICLE I. All moneys or other funds received by the Society for the purpose of obtaining and maintaining a building for headquarters for the Society shall be kept by the Treasurer in a separate fund known as the "Building Fund."

ARTICLE II. Any interest obtained from the investment of said funds may be used as a whole or in part to pay rental for quarters to be used by the Society for central activities.

ARTICLE III. Any interest obtained from the investment of said funds and not used to pay rental as specified in Article II shall be added to the principal of the "Building Fund."

ARTICLE IV. The principal of said funds may be expended only to acquire real property to which the Society shall hold title.

The committee is of the opinion that this vote, while it continues to stand, precludes the possibility of using the earnings of the building fund as a gift.

In arriving at its recommendations in this matter, the committee calls to the attention of the Council the availability, without extra charge, of John Ware Hall, Sprague Hall, the Prince Room and the Supper Room for the activities of the Society, and the ever-increasing use which is being made of these facilities. It points out how important it is that the offices of the *Journal* be contiguous to the library itself. It finds some disposition to regard the present headquarters as a permanent home provided additional office space is made available for the use of the Society in its attempt to better serve its membership. Such are some of the conclusions which have influenced the committee in presenting these recommendations.

In connection with these recommendations, may I read a letter from Dr. William C. Quinby, which came too late to be considered by the Executive Committee but which is presented at the direction of the President.

To the Council of the Massachusetts Medical Society:

The Boston Medical Library through its Board of Trustees has directed me as treasurer to bring to your attention the matter of the facilities which the Library furnishes the Massachusetts Medical Society and the present need for a readjustment of the terms of the agreement now existing between them.

The desire of the Society for more space having been noted, the Library, to this end, has available the space now used by the *Journal of Bone and Joint Surgery*, consisting of a sizable room on the front of the building and a smaller office across the hall. With the addition of these rooms the Society will have at its disposal all the space to the right of the entrance hall on the first floor of the Library building.

In addition to space under permanent occupancy by the Society it is important to point out that the facilities of Ware Hall, Sprague Hall, the Prince Room and the Supper Room, will be, as in the past, at the command of the Society for those of its meetings as need such accommodation. Also, one half the space in the Library's fireproof vault is reserved for the use of the Society.

For these facilities the Library will charge the Massachusetts Medical Society the sum of \$6500 (sixty-five hundred dollars) as annual rental.

A suggested form of agreement is appended.

WM. C. QUINBY, Treasurer
Boston Medical Library

The committee reviewed and approved the report of the Committee on Medical Defense and that of the Committee on Expert Testimony and approved both.

The committee commends the report of the Committee on Public Relations to the attention of the Council.

The Council, on February 3, 1943, referred the matter of supplying the armed forces with the *Journal* to a joint conference between the committee and the editors of the *Journal*. Dr. Nye reported that the Army had already approved of a plan to subscribe to the *Journal*, placing a copy in every Army hospital of twenty-five beds or over. He further reported that this will amount to between 450 and 500 subscriptions. He added that the Navy could use 100 copies. The cost to the Society of the latter would be about \$400. A motion to send 100 copies to the Navy free was defeated.

The Executive Committee, on February 3, 1943, was directed by the Council to consider some method of attendance that would cause councilors to remain until the business of the Council is completed. The committee in this connection recommends that the stated meetings of the Council, other than the annual meeting, convene at 10:00 a.m. and, while there is any business to transact, do not adjourn for lunch until 2:00 p.m.

The committee acknowledges the receipt of a communication from Dr. Charles F. Wilinsky et al. of the staff of the Beth Israel Hospital. With the communication is included a protocol governing a plan for the care of the practices of such members of its staff as have or will enter the armed forces. The communication seeks the approval of the Massachusetts Medical Society. The committee recommends that this matter be referred to the War Participation Committee and that this committee report on this matter at the next meeting of the Executive Committee.

The committee, taking notice of the growing importance of anesthesia and the wisdom of encouraging in every way possible those who are engaged in its development, recommends that the Committee on Arrangements be instructed to provide for an exhibit and a lunch on meeting on anesthesia and for the suitable advertising of this exhibit and meeting in the annual meetings of the Society.

The committee received a letter from the National Conference on Medical Service, including a resolution which this body proposes to have offered in the House of Delegates of the American Medical Association at its meeting next month.

Investigation has shown that this conference springs largely from the Middle West. It could seem to be a bit dissatisfied with the scope of the activities of the Bureau of Medical Economics of the American Medical Association. It would substitute for this bureau a committee on medical service to be made up of the president of the American Medical Association *ex officio*, the immediate past president of the American Medical Association, the secretary of the American Medical Association *ex officio*, a member of the Board of Trustees of the American Medical Association, designated and selected by the Board of Trustees, and one member of the American Medical Association elected as hereinafter provided from each of the following nine geographical subdivisions of the United States:

NEW ENGLAND	MIDDLE ATLANTIC	EAST NORTH CENTRAL
Maine	New York	Ohio
New Hampshire	Pennsylvania	Indiana
Vermont	New Jersey	Illinois
Massachusetts		Michigan
Rhode Island		Wisconsin
Connecticut		
SOUTH ATLANTIC	EAST SOUTH CENTRAL	WEST SOUTH CENTRAL
Delaware	Kentucky	Arkansas
Maryland	Tennessee	Louisiana
District of Columbia	Alabama	Oklahoma
Virginia	Mississippi	Texas
West Virginia		Panama Canal Zone
North Carolina		
South Carolina		
Georgia		
Florida		
Irrito Rico		
WEST NORTH CENTRAL	MOUNTAIN	PACIFIC
Minnesota	Montana	Washington
Iowa	Idaho	Oregon
Missouri	Wyoming	California
North Dakota	Colorado	Alaska
South Dakota	New Mexico	Hawaii
Nebraska	Arizona	Philippines and
Kansas	Utah	Pacific Islands
	Nevada	

The resolution provides:

The members of the House of Delegates from each of the foregoing geographical subdivisions of the United States shall elect one member of the American Medical Association to serve on said committee three of said nine members shall serve for one year three shall serve for two years and three shall serve for three years the respective terms of office of the nine members first elected shall be decided by lot and thereafter the said terms shall be for three years

each, the expiration date for the first one year term shall be at the next ensuing annual session of the House of Delegates of the American Medical Association, expiration dates for all terms shall coincide with the dates of the regular annual session of the House of Delegates of the American Medical Association.

The resolution defines the duties of such a committee under seven headings:

(1) The making available of scientific facts and data and medical opinion with respect to timely and adequate rendition of medical care to the American people.

(2) To integrate the activities of the Committee on Medical Service with respective state and county committees on like activities.

(3) Establish relationships and cooperation with other allied groups who are likewise engaged in the rendition of medical care, in its various branches, to the American people.

(4) The Committee on Medical Service shall hold at least two meetings per year one shall be held at the time and place of the annual meeting of the House of Delegates, the other meeting shall be held in the City of Washington, D. C., and called at the direction of the chairman, and such other meetings as may be necessary to be called by the chairman upon the written request of the majority of the committee.

(5) The committee shall forthwith and annually thereafter elect from its own membership a chairman and a vice-chairman.

(6) The Committee on Medical Service shall establish and maintain an office in Washington, D. C. and shall further be empowered and directed to employ a full time executive director, who shall act as secretary of the committee, and, whose duties shall be specified by the committee. Such executive director shall be a physician who has been actively engaged in the private practice of medicine for not less than five years during the previous ten years, and furthermore be informed and qualified to act as a liaison representative of said committee.

(7) The Committee on Medical Service is further authorized to hire such legal and administrative help as is necessary.

The resolution adds that the work of this committee shall be supported by an appropriation from the American Medical Association of not less than fifty cents and not more than one dollar for every member.

The communication called on us to instruct our delegates to support the resolution. The Executive Committee reports that it has not sufficient knowledge of this matter to enable it to recommend that our delegates be instructed to either favor or oppose this resolution. The committee recommends that the resolution be referred to our delegates without prejudice.

A list of appointments for the year 1943-1944 submitted by Dr. Roger T. Lee president-elect was approved. This list will be read by Dr. Lee later in the evening.

MICHAEL A. TIGHE Secretary

APPENDIX NO. 4

REPORT OF THE COMMITTEE ON MEMBERSHIP

The suggestion of the Massachusetts State Committee of the Procurement and Assignment Service, of which Dr. Reginald Fitz is chairman, is as follows:

A curious finding has arisen which it seems to me deserves consideration. Approximately 1900 Massachusetts doctors have commissions or have had commissions with honorable discharge in one of the branches of the armed forces. Of these 1900, only 1050 are members of the Massachusetts Medical Society. Of the 850 commissioned officers who are not members of the Society, 200 in round numbers are substandard school graduates and not necessarily desirable for the Society to worry about. That leaves a pool of about 650 young men who represent sort of a floating medical population.

In this pool are interns, residents, fellows, junior teachers in medical schools who come here for two to three years and such people. Potentially, in normal times, they represent a valuable part of our medical population because practically all are engaged in full-time work or are active in research or teaching. I raise the question as to whether the Society and the Boston Medical Library might not make some effort to attract men of this type.

Could we not offer some sort of a junior or temporary membership to both organizations at a reduced fee, and would it not be worth while for these organizations to stir themselves up in order to make their work as appealing as possible to men of this type? What is your thought on the matter?

The Committee on Membership initially, on consideration of the above, was very much in favor of the creation of a new form of membership which might be called a "junior membership," rather than a "temporary membership" or an "associate membership," because we already have in the Massachusetts Medical Society a classification known as "associate fellowship," an honorary grouping; but the committee believed the Society should know what need of such membership existed, to what extent such membership would be utilized in the Commonwealth and exactly what privileges and duties would accompany such membership. It was thought that junior membership must be, at least for the time being, confined to physicians who have graduated from approved schools only. From oral contact with some of the trustees of the Boston Medical Library, it developed that a junior membership in both the Massachusetts Medical Society and the Boston Medical Library, at a reduced fee as suggested by Dr. Fitz, was not feasible or workable. Accordingly, the committee has attempted to clarify the establishment of junior membership in the Massachusetts Medical Society alone and not in combination with any other organization.

There can be little doubt that there is a pool of young physicians, largely interns and residents in hospitals, these physicians not being members of the Society. Your committee has attempted to contact such physicians in the major Boston hospitals and some of the outlying metropolitan hospitals. We have found in our conversations with these groups of men that there was not an excitable interest to join the Massachusetts Medical Society at this time. The *Journal* is available to nearly all these men. The internship at present allowed by the

Government is of one year duration only. The majority of men are financially embarrassed. They feel their future is so uncertain that they have expressed little or no interest in junior membership in the Massachusetts Medical Society, irrespective of privileges granted or duties involved. Hence, the need or the utilization of such new form of membership by this particular intern group of physicians seems to the committee to be exceedingly small.

In order to clarify the rights, prerogatives and duties of such membership, if established, Dr. Fitz and the chairman of the committee have communicated with Dr. Olin West, secretary of the American Medical Association, relative particularly to two points, namely, Would junior membership in the Massachusetts Medical Society, applied to young physicians of not more than five years out of medical school and graduates of approved schools carry with it automatically membership in the American Medical Association? Would the American Medical Association grant its journal or one of its publications to such members at any reduced rate under the regular subscription fee of \$8.00 per year?

Dr. West has informed us in writing that there are intern members in the Chicago Medical Society, who have the right to attend meetings only, and that other component societies have established junior memberships for the benefit of young men who have completed intern service and have been licensed to practice but find it difficult to pay regular membership dues. There have also been established a few associate memberships in some state societies, but the number of component societies who have established such classification are few. To quote from Dr. West:

My information is to the effect that not any intern members or junior members or associate members of the kind referred to above are entitled to vote or to hold office and that the names of the members of those special groups are not reported to the secretary of the constituent state medical associations immediately concerned for enrollment as members of the state associations. Associate members of constituent state medical associations *are not* supposed to be reported to this office for enrollment as members of the American Medical Association unless they have all the privileges accorded to active members under the constitution and by-laws of the individual constituent state medical associations immediately concerned.

Dr. West further states that it is improbable that the journal or one of the other American Medical Association publications could be furnished to any physicians at less than the set cost of \$8.00 per year.

It is therefore clear that junior membership would not carry automatically membership in the American Medical Association.

The committee further believes that it would be impossible to establish a junior membership on any financial basis less than that commensurate with the cost of the *Journal*. It seems obvious that such membership would not allow the holding of office but would carry with it attendance and participation in the meetings of the Society.

Bearing in mind the results of its investigations, as briefly outlined above, the Committee on Membership favors in principle the establishment of a junior membership for physician graduates five years or less of approved medical schools, but does not think that this

is the time for the establishment of such new class of membership because of unsettled war conditions

HARLAN F. NEWTON, *Chairman*

APPENDIX NO 5

REPORT OF THE MASSACHUSETTS STATE COMMITTEE OF THE PROCUREMENT AND ASSIGNMENT SERVICE FOR PHYSICIANS

The Massachusetts Medical Society may well feel proud of the record already made by young Massachusetts doctors in the present war.

Captain Edward Mozes, of Malden, was in the fighting at Guadalcanal. He was a battalion medical officer, responsible for collecting the wounded of his unit, caring for them as best he could, and for evacuating them. The country was hilly, in ridges, dipping in and out of steep and treacherous ravines, so that all medical equipment and supplies had to be carried by hand. The enemy was within easy range, pestering our men with machine gun fire, mortars, artillery and sniping. Captain Mozes organized his detachment effectively under these circumstances, he performed a leg amputation and gave plasma to a number of patients in the field, he developed a small advanced hospital for the immediate treatment of those who developed malaria, and when ever his battalion moved he always was in column with his men, ready to handle any emergencies that might arise. Clearly, he set an unusually fine example of intelligent and fearless work in very trying conditions.

Lieut. John T. Roach, of Jamaica Plain, was a medical officer on the *Lexington* in the Coral Sea. With utter disregard for his own personal safety he treated the wounded on his ship and directed the removal of casualties from a dark and smoke-filled compartment frequently shaken by violent explosions. His outstanding conduct, his cool courage and his professional skill undoubtedly saved the lives of a great many men who must inevitably have perished without his assistance.

In French Morocco, Lieut. Charles P. Roberts, of Boston, another naval medical officer, administered plasma to a severely wounded soldier under direct shell fire and bombing. As in the case of Lieut. Roach, he too appeared entirely unconscious of his own safety as he carried on his work.

One reads, with great respect, such reports of the gallantry which our young men are displaying, because although these isolated episodes happen to have been described in the newspapers, they are typical of what our medical officers are doing quietly and inconspicuously wherever there is need.

Hearing that there were a number of wounded men lying in front of his Aid Post, this officer went forward under heavy shell fire and, regardless of his own personal safety, attended to them. By his action and bravery the lives of many men were saved.

This was said in 1918 of one of the present members of the Council. It gives a feeling of pride to know that our young medical men of today are chips of the old block and that they are upholding the traditions of medical service which have been passed on to them by their seniors.

Editorials have appeared in the *Journal of the American Medical Association* and the *New England Journal of Medicine* recently, commenting on the urgent and immediate needs for more officers from this part of the country. Whether one agrees or disagrees with the computations involved is beside the point. The fact remains that the Army and Navy are asking for more medical officers.

The 1942 *American Medical Directory* credits Massachusetts with 8085 doctors. Of these, the Society claims as members 5351. Thus there are two distinct pools of medical men in the State—those who belong to the Massachusetts Medical Society and those who do not.

The latter group comprises 2734 physicians. In this pool are young men who are graduates of medical schools approved by the Surgeons General but who have not applied for admission to the Society, a number of graduates of substandard schools who are ineligible for membership in the Society under our present by-laws but have obtained commissions, a residue of older physicians for whom the armed forces have no need, and a group of younger men who are licensed to practice medicine in Massachusetts but are not commissionable for a variety of reasons. This particular source of medical officers is now nearly used up. It appears to have yielded 1269 officers and cannot be expected to supply many more.

Officers to be commissioned in future, therefore, must be derived almost entirely from the ranks of our own membership except in the case of the very young men who are commissioned as medical students. These men, as they complete their internships, will enter the armed forces automatically.

The War Manpower Commission talks in terms of ages, grouping doctors under thirty-eight years old in one class, those between thirty-eight and forty-five in another, those between forty-six and sixty-four in a third, and those over sixty-five in a fourth. In a war such as the present, doctors who are most youthful make the most desirable officers. A sampling of the age of 1900 medical officers drawn from Massachusetts shows that 67 per cent were under thirty-eight years old, 22 per cent between thirty-eight and forty-five, and 11 per cent were between forty-six and sixty-four. Another way of saying this is that in the medical corps of the Army and Navy the youngster in his early thirties is encountered six times as frequently as is the venerable old man of fifty, and three times as often as is the middle-aged doctor in his forties. The chances are, too, that, on the whole, in warfare the medical man's usefulness is inversely proportional to his years.

We have in the Massachusetts Medical Society 1269 (24 per cent) doctors under thirty-eight years of age, 1128 (21 per cent) who are between thirty-eight and forty-five, 2032 (38 per cent) who are between forty-six and sixty-four, and 891 (17 per cent) who are more than sixty-five. The distribution of age groupings varies to a certain extent in the different districts, although the general trend is identical, universally among our members there are more older men than younger men.

A graph has been constructed which shows how the members of the Society in different age groups have been classified by your committee (Fig. 1). Nearly every member in the Society has now been labeled 'available' or 'essential', and in the case of the 'availables', as being in one of the services, or having been rejected as unfit.

for military service by one of the surgeons general, or as still being potentially commissionable.

The forty-five-to-sixty-four group can be dismissed very promptly. Men in this age group who wish to volunteer are likely to do so, and it makes little difference to them who wishes to call them essential. On the other hand, except in occasional instances, their services are unlikely to be more useful in the Army and Navy than

FIGURE 1. Analysis of the Membership of the Massachusetts Medical Society.

in civilian life, and neither branch of the service will put any pressure on men of this age to join.

Doctors in the age group between thirty-eight and forty-five are more problematical. To be sure, as already stated, they are likely to be less useful, by and large, than younger men, but on the other hand, they still can make very desirable officers. They are apt to find it a difficult matter to uproot themselves from civilian life for they are well established. Many are qualified specialists. One of the important pieces of work to be done will be to analyze each of the availables in the group in our membership with a view of determining how many and which ones should be encouraged to volunteer.

The youngest age group, those doctors under thirty-eight years old, are the ones most keenly sought by both Army and Navy. The majority of doctors from Massachusetts who enter the Army or Navy during the next few months should come from it, and it is here that are encountered many perplexing problems. Here are men who have been called essential and, whether justifiably or not, may require investigation. Here, in any city or town, is the residue of available men who appear to become increasingly essential as time goes on, whereas had they obtained commissions earlier nobody would have noticed their absence. Here are encountered patriotic young men and themselves weighed down by a variety of family problems and need advice regarding things to do.

Another graph has been constructed which reveals the uniformity with which the different districts have supplied medical officers (Fig. 2). It is apparent that our members have gone into the Army and Navy from the

FIGURE 2. Graph to Show the Manner in Which the Different District Societies Have Supplied Medical Officers.

The ratio between population, membership and officers supplied is relatively uniform.

different districts in about equal proportions and that so far local Procurement and Assignment committees have used nice discrimination in avoiding any serious medical depletion. The problem that remains is to determine how many of those left in each district should be pressed into national service. Obviously, the largest numbers must come from the largest district societies.

On the ratio of doctors to population we still have more doctors than we need. Although a number of our young men have left the State, the health of the people does not show evidence of having been injured thereby. Nor does the additional load of work thrown on the older physicians who have stayed behind appear to have been harmful. During 1940, 1941 and 1942, the Society lost each year by death about a hundred members, and during the last twelve months only seventy-five. Thus Massachusetts seemingly can spare more doctors.

Since the last meeting of the Council a plan to accelerate enrollments has been proposed by the War Manpower Commission. Stated briefly, the plan, as it might be adopted here, is as follows:

Henceforward, a physician who is declared available to apply for a commission and does not do so will receive written notification from the Massachusetts Medical Society in these words:

Dear Doctor

You have received notification from the Procurement and Assignment Service for Physicians of the War Manpower Commission that you have been declared available and inviting you to apply for a commission. You are requested to appear at _____ on _____ when your case will be reviewed by a committee of the District Medical Society.

Each district medical society will be asked through the President of the Massachusetts Medical Society to establish a reviewing committee. This committee will be composed of older men of unquestioned impartiality and character. One of them will serve as presiding officer of the committee, and another will act as secretary and recorder. The president of the district medical society, the president of the Massachusetts Medical Society and the chairmen of the local Procurement and Assignment committees will be members of such reviewing committees *ex officio*.

Such committees will attempt to interview all available men in each district as the names are submitted, explaining the need of the armed forces for medical officers and a physician's obligation to volunteer. If a doctor does not wish to volunteer, for any reason, the committee will hear his arguments. If the committee believes that a man classified as available should not enter the armed forces, it shall say so. On the other hand if it believes that a man should volunteer, it shall so inform him. The recorder of each committee will keep the chairman of the War Participation Committee of the Society informed of its decisions, and the latter committee will in turn report to the Massachusetts State Committee of the Procurement and Assignment Service for Physicians. Final opinion is to a man's availability will continue to rest in the Corps Area Committee.

If a man declared available does not apply for a commission within ten days after his case has been considered in this fashion he will be reported to the state director of Selective Service, with a request for his reclassification.

This plan, which amounts to establishing a mechanism for the direct solicitation of medical officers by the Massachusetts Medical Society through each of its district medical societies, offers the threat of possible depletion of medical manpower from overzealous recruiting. Your committee believes, however, that the plan can be made to operate safely and effectively.

Your committee, therefore, begs leave to conclude this report with the following resolution:

WHEREAS The War Manpower Commission has announced that there is immediate need for more physicians to serve as medical officers in the armed forces of the United States, and

WHEREAS The War Manpower Commission has announced that Massachusetts should supply more medical officers than have so far been commissioned from the State and

WHEREAS A plan has been suggested by the War Manpower Commission through which the enrollment

of medical officers may be accelerated with the help of county or district medical societies in certain states, therefore, be it

RESOLVED, That the Massachusetts Medical Society support this plan, and be it further

RESOLVED, That reviewing committees be established by each district society, the members of which shall be nominated by the district society presidents and appointed by the president of the Massachusetts Medical Society. Such committees shall serve for the general purposes outlined in this report.

REGINALD FITZ CHURCH

APPENDIX NO 6

REPORT OF THE COMMITTEE CONCERNED WITH PREPAYMENT MEDICAL CARE COSTS INSURANCE

Carrying out the understanding that I should bring periodic reports of progress, I present an interim report utilizing the time given to the Committee Concerned with Prepayment Medical Care Costs Insurance.

I shall first discuss the present status of Massachusetts Medical Service. There is, of course, the question, which is always pertinent as to the desirability of the present time for starting such a program. There is a difference of opinion on this matter. The State Department of Insurance believes that this is a favorable time, but other groups maintain that owing to the change in the economic status of the working family, this is not a desirable time. However, an attempt to present the program effectively to the public has been started in recent months. In January there were a few samplings in the Boston area. It is only since the last week in February that an effort to sell the whole state was undertaken. Since a few months are needed to begin the work of interesting groups before a sales campaign can become effective, it really means we are just starting underway to procure subscribers.

There are different factors which bear and will bear on the growth of this organization and I just want to outline them as quickly as I can under four headings. If you carry these headings in your mind, it will give you a better grasp of our problems. The first relates to the whole organizational activity, the second relates to the type of contract, the third relates to sales problems and the fourth relates to income limitations established by the Society.

Regarding organizational activities there is a matter which is known to the voting members relating to the \$75,000 which the Council so generously voted and made available to the corporation. The Commissioner of Insurance ruled that only \$5,000 of that shall be available to start the corporation and that \$70,000 shall be held by a bank in trust, to be used only with his approval in a letter bearing his signature and when we have a surplus of \$25,000. So that you can see we are really starting in under a very definite handicap and I feel that the Council should know that \$20,000 of the \$25,000 is retained in the bank earning interest. Then there is the requirement that out of first year premiums a 25 per cent reserve shall be set aside. This is not available either for meeting the expenses of the corporation or for paying the physicians. In the face of these facts it is very evident that we can work only to a certain point at which premiums must begin to grow adequately to carry us along.

Regarding another angle bearing on that point, we have been working in close co-operation on a contract basis with the Blue Cross. Much of the \$5000, as you must realize, has been used up in the initial printing and miscellaneous expenses incidental to starting the program. Outside of that, there has been the contribution of a tremendous personal effort by the members of the Blue Cross organization. That effort has been given most generously, but it is very evident that there is a point beyond which we cannot pass, so far as that personal contribution is concerned. The question has not yet been raised, but certainly it is common sense that our premiums must begin to accumulate to that point where they will meet the percentage requirement that will be due the Blue Cross group for sales effort and organizational activities. Certainly that is not in sight yet.

The problem of sales is definitely related to the fact that the salesmen of the Blue Cross organization have only a limited amount of time that they can give to the Blue Shield program. In order to augment the growth of the Blue Shield a quota has been established for the salesmen. For the Blue Cross their monthly quota shall be 500 subscribers; and 100 for the Blue Shield. With this quota basis it is hoped there will be increased effectiveness in selling the Blue Shield program.

Among the organization activities there is the question of reaching the profession. We have at the present time 4500 men in the state in active practice, and it is a difficult problem to get all information to them so that they can effectively understand it and make up their minds whether they are going along with the program. The chief approach in the past, as you know, has been personal—last year through speeches to the county societies, and then through the distribution of information to the members of the Society in the form of statements in the *Journal*; there has also been some degree of publicity in the papers. At present it is difficult to carry on much publicity because of the fact that there is not a great deal of sales achievement to which publicity can be related. Also, with reference to the profession is the very pertinent problem of the nonacceptance of the corporation by some doctors, which is related to several very evident facts. First, there are groups of physicians who have not become persuaded that the prepayment plan offered by the Medical Society is a necessary program. Then there is a group which questions the type of contract, feeling that the basis of surgical and obstetric coverage is not broad enough. Third is the nonacceptance of the fee schedule by a definite proportion of the men. Then there is the fact that some of the men who are nonparticipating physicians hinder the sales of contracts to prospective groups by reason of their own nonparticipation.

The second factor is the type of contract. I shall not go into it extensively, but it requires brief reconsideration. There are, of course, only three definite approaches possible on the present basis of experience. One is the complete medical-care contract, another the complete hospital coverage, and the third is surgical-obstetric coverage in the hospital. As you look across the country you see that there has not been a successful move by a state medical society to offer a complete-coverage contract. Oregon is the only one at present which is active in this respect, but on a county basis. Others have moved away from it even to the extent of giving up their program of complete service coverage and adopting surgical-obstetric programs on a cash-indemnity basis. There has been some renewal of interest in Cali-

fornia and Buffalo in complete coverage simply because of the fact that the Government is participating with the medical groups in starting such service to cover war industries and housing projects. The complete hospital coverage so far is being undertaken only by New Jersey; it was tried and given up in Buffalo. The number of policies of this character sold do not indicate yet any increase in interest as compared with a surgical-obstetric contract. Concerning the latter, with which we have started, it is unfortunate that, since in other states 69 per cent of payments are to general practitioners, it has been misinterpreted through the state as a specialists' program.

Regarding the third factor, the sales program, there is one big item of importance which enters into the problem so far as the support of the profession is concerned, and that is that experience across the country shows that in order to avoid financial difficulties with the program a very definite percentage requirement is needed to enroll any single group. This ranges from 50 to 75 per cent. We are attempting to liberalize some of these requirements. But it is well to keep in mind that lacking care we can repeat the experience of a large state on the western coast, where the program has cost them already \$100,000; and in Michigan the deficit was, until recently, over \$500,000. They have gradually reduced this to \$365,000. Nonparticipation by physicians may limit the appeal of the program so that it will be difficult to meet percentage requirements.

With regard to the fourth factor, the problem of the limitation of incomes, that relates particularly to the change in status of the workmen in the state. We established the income limitation for the service benefits, that is, no extra charge by the physician, at \$2000 for the individual and \$2500 for the family. A recent report on this state shows a marked increase in the average earnings in certain districts, so that the question of whether we can procure a cross-section enrollment is before us. The average income today in the state is \$41, which makes an income of \$2050 for the year. When we check that against the percentage requirement for enrollment of certain groups, it is questionable whether the percentage can be procured. In certain sections it would seem too many workers would be out of the picture. That is so with the \$49 weekly earnings average which now applies to Beverly; and in Worcester, the average income is \$47 per week. As I evaluate the service offered and the problem of enrollment percentages, those in the low-income group may not enroll; the high-income group does not seem to be keenly interested in cash indemnity without protection; and the middle-income group, the group earning from \$2000 to \$2500, is not now a large enough group to meet the percentage requirements for enrollment.

The question will arise, if the present situation continues, whether the Society should consider doing something with reference to the income levels. There are only three possible approaches other than maintaining them at their present levels or increasing them slightly, say to \$3000 for the large family. One is that there be no ceiling, as in Oregon and Buffalo. The other is to have a second higher premium structure and fee schedule for upper-income groups. That is like Dr. Elliott's plan in New York, which has not yet been very effective. The third is that the Society might consider the question of adding to the present service base an arrangement for a fixed additional charge—a ceiling charge over and above

the fee schedule applicable to the \$4000 or \$5000 groups, beyond which they would agree not to go. Finally, a reconsideration of a ward contract discussed in committees but not presented to the Council will be called for in the future.

I simply call these facts to your attention for future consideration. They may present serious questions depending on what happens to the program in the light of experience in the next few months. As a basis for recommendation I should first simply suggest that this present setup be given a thorough trial, as far as the sales effort is concerned, for several months, and that we keep close watch to determine whether or not it is beginning to carry itself on the basis of contracts sold and premiums earned. Then if any change is desired it should be definitely related to a careful study of experiences elsewhere and an evaluation of the validity of those experiences as they are related to our state program. If possible we must seek to procure more definite co-operation and understanding by the profession through continued approach to them so that all may understand how vital it is for us to achieve success with this program.

JAMES C. MCCANN, *Chairman*

APPENDIX NO 7

REPORT OF THE COMMITTEE ON CANCER

Your interim chairman of the Committee on Cancer is deeply sensible of the honor which appointment to the position so long and so ably filled by Dr. Shields Warren has conferred upon him. Having held this office but a few weeks, his report can hardly be as comprehensive as could be desired; nevertheless he wishes to report the work of the committee to date. It was not possible to file the report for prepublication because of the shortness of the interval between appointment and the time the report was requested by the Secretary.

A meeting of the committee was held at the Hotel Sheraton Boston, on May 7. Drs. Simmons, Truesdale, Daland and Hunt were present.

A hearing was given to Mr. H. D. Fish, assistant managing director of the American Society for the Control of Cancer, Incorporated, who presented a plan for lay organizations in the large centers of population to extend the work of popular education in co-operation with the state program and backed by the experience and facilities of the Society. After free discussion, the committee decided that it was inexpedient to launch the suggested plan at this time.

Dr. Herbert L. Lombard, director of the Division of Adult Hygiene, Massachusetts Department of Public Health, was present by invitation and submitted the following statement in regard to the educational program of the department:

The exigencies of war have seriously interfered with the cancer education program in this state. This is particularly true concerning the activities of the co-operative cancer-control committees. The absence of many physicians, the scarcity of gasoline and the inherent dangers of the blackout have resulted in a greatly diminished number of cancer meetings. The realization that the situation might become more acute, combined with the need for a continuation of some type of cancer education during the period of war, prompted a two-day symposium to discuss means and methods of carrying on the educational campaign.

The participants in the symposium included Professor Edwin B. Wilson, Dr. Shields Warren, Dr. Ernest M. Daland, Dr. Ira T. Nathanson, Dr. Clifford C. Franseen, Dr. Ernest L. Hunt, Mr. Ernest Stephens, Mr. Richard J. Schumoyer, Mr. Winthrop L. Webb, Mr. George L. True, Mr. W. O. Johnson, Mr. Arthur D. Thomson, Mrs. Florence Parker, Mrs. Dorothy Averhill, Miss Margaret Allen, Mrs. Hilda LaRocca, Miss Mary M. Hurley and other members of the staff of the Division of Adult Hygiene, Department of Public Health.

As a result of the symposium a booklet, *Cancer: The what, whether, how*, has been prepared which can be used either by the co-operative cancer-control committees or by schools desirous of helping in cancer education. A monthly bulletin, *Cancer Tidings*, is being sent to the central committees, both to maintain their interest and to further cancer education. In so far as possible the regular talks of the co-operative cancer control committees have been given but there has been a distinct decrease in their number.

The cancer situation in Massachusetts, however, improved in 1942. The interval between first symptoms recognized by the patients and consultation with the first physician was the lowest it has ever been. The adjusted death rate for females again dropped and has now returned to the level of 1913.

It is very gratifying to record the continued interest of so many people in the cancer program in spite of their many other activities.

Dr. Channing Simmons reported on state-aided cancer clinics, particularly in relation to the changes and progress growing out of the survey which he conducted last year, the details of which were reported to the Society through the *Journal* (September 17, 1942) and formed part of the report of this committee at the October meeting of the Council. In that report he criticized seven clinics and made certain suggestions which have been carried out, so far as possible by the Department of Public Health. The Quincy Clinic has been discontinued. The Newburyport Clinic is essentially combined with that of Beverly at least for the duration of the war. The Hyannis Clinic is unsatisfactory. The attendance has fallen off lamentably since the shortage of gasoline. One surgeon strives to keep it going because it is geographically important and affords a limited opportunity for carrying on educational work. The Pittsfield Clinic was discontinued by vote of the local medical society. This is unfortunate considering the geographical situation of the city. Transportation to Westfield is good. However, reorganization of the Brockton Clinic by the Plymouth County Cancer Committee has taken place, and it is now conducted on lines very closely approximating the standards defined by the Department of Public Health. It is the belief of clinic chief, Dr. G. A. Moore, that changes effected will make for more efficient service to an increasing number of patients. Concerning the Greenfield and Springfield clinics details on which to base an estimate of progress from the situations considered unsatisfactory in the 1942 survey have only today come to hand and show definite gains since the date of the survey.

All the clinics suffer from losses to the armed services of staff personnel but are carrying on as best they can. Many older men have taken over the work of their

younger colleagues, and volunteer nursing and clerical aides have helped in those phases of the clinic service.

In spite of the handicaps imposed by wartime conditions it is believed that there must be no letup in the cancer-control effort. It is the opinion of your committee that a greater awareness of his opportunity on the part of every individual physician practicing in the State could do much to offset the loss of trained workers in the clinics. Such awareness should be acquired by the physician by drilling himself in the habit of requiring the completion of a diagnosis in all cases that present any symptom or sign which may by any possibility be due to cancer. Definitive diagnosis without undue delay is the desideratum. Nothing less can square with the doctor's sense of duty to his patient.

Fortunately such are the standards of most doctors. The progressively shortening intervals between the time of seeking advice and the receiving of definitive treatment as revealed by the experiences of the state clinics shows that physicians are more and more generally living up to the demands of the situation and are, moreover, taking active part in spreading the gospel of early diagnosis through personal contact with their families and by talks to lay groups which now abound in every community.

As the medium through which the benefits of modern medical science shall become available to the individual citizen it is our conviction that there is no substitute for the well-educated, experienced, conscientious doctor.

ERNEST L. HUNT, *Chairman*

APPENDIX NO. 8

REPORT OF THE MILITARY POSTGRADUATE COMMITTEE

The Military Postgraduate Committee held its first meeting on November 6, 1942, when plans were made to provide postgraduate extension courses for the Army and Navy medical officers who are stationed within the Commonwealth. Colonel J. J. Reddy, chief of medical operations of the First Service Command, and Captain H. L. Kelley, chief of medical operations of the First Naval District, had already welcomed the offer of the Society and advised the committee to proceed to arrange a curriculum and organize a teaching staff. At this meeting the committee conferred with officers representing the medical staffs of Fort Banks, the Chelsea Naval Hospital, Camp Edwards, Fort Devens, the Portsmouth Navy Yard and Westover Field. As a result, a curriculum was developed and a faculty organized. The plan of postgraduate instruction included clinics and ward rounds with the instructor acting as a consultant, supplemented by formal and informal lectures.

The committee is unanimous in reporting that this project has been well worth the effort and expense. Much has been learned in regard to the postgraduate needs of the medical officers of the armed forces, as well as about the methods of presenting the subject matter. Each session has been an ordered military formation, so that the attendance has been practically 100 per cent. Our civilian instructors have learned that punctuality and thorough mastery of the subject matter are necessary to meet the exacting demands of wartime medicine.

On May 20, 1943, the committee held a second joint meeting with representative medical officers from the various Army and Navy posts. The work of the past winter was reviewed; constructive criticism was received from each of the medical officers present. The committee's work has been greatly facilitated by comments and suggestions from these officers during the past season. Some of their comments will be of interest to the Society.

Westover Field. Colonel Schwichtenberg and Lieutenant Staples report that clinical case teaching and informal ward rounds at the Station Hospital before the lectures have helped greatly in holding interest and making the teaching more practical. They consider the course highly successful and heartily thank the Society for providing this postgraduate program.

Camp Edwards. Lieutenant Colonel John C. Eckels and Lieutenant Colonel Lewis W. Hill gave an enthusiastic account of the postgraduate courses at their camp. They find that the time spent in going to the postgraduate programs is very much worth while. They wish to inform the Society that a camp commanding officer may detail any medical officer for ten days' residence instruction without cost to the Government at any time; they hope that the committee will find it possible to provide for such residence postgraduate instruction during the coming year. They expressed the appreciation of all their medical officers for the work of the instructors.

Fort Banks. Major R. Earle Glendy gave a review of the postgraduate courses offered at their hospital; the interest has been above average, and they request a continuation of the courses on a year-round basis, if possible.

Portsmouth Naval Hospital. Commander Eugene H. Drake reported that they greatly appreciated the courtesy of the Society in sending an instructor to their hospital and hoped further prograduate instruction could be provided for the Navy.

Lieutenant Commander James M. Faulkner, of the Chelsea Naval Hospital, cited the large naval hospital at the Quonset Air Base in Rhode Island and asked if the Society could be persuaded to offer instruction there.

Fort Devens and the Chelsea Naval Hospital have been handled by members of local medical societies; since these programs had already been arranged, your committee had nothing to do with them officially, although several of our instructors attended the meetings. The officers at these posts report that they will probably use the Society's teaching facilities another year.

The committee had a budget of \$350; \$235.07 has been spent for necessary expenses, leaving a balance of \$114.93. Both the Army and Navy extend their thanks to these busy teacher physicians who donated their time.

The medical officers in charge of the postgraduate courses are as follows: Fort Banks, Major R. Earle Glendy; Chelsea Naval Hospital, Lieutenant Commander James M. Faulkner; Fort Devens, Colonel Gilbert T. Hyatt; Camp Edwards, Colonel C. W. Riley; Lieutenant Colonel John C. Eckels and Lieutenant Colonel Lewis W. Hill; Portsmouth Navy Yard, Commander Eugene H. Drake; Westover Field, Colonel Albert H. Schwichtenberg and Lieutenant Charles Staples.

Twentyseven instructors gave a total of thirtythree sessions as follows:

DATE	SUBJECT	INSTRUCTOR
FORT BANKS		
Nov 13	The Importance of an Unstable Blood Pressure in Applicants for Military Service	Dr Robert W Wilkins
Nov 20	The Importance of Renal Glycosuria in Applicants for Military Service	Dr Howard F Root
Nov 27	The Management of Peptic Ulcer Patients	Dr Franklin W White
Dec 11	Blood Plasma as a Therapeutic Agent	Dr Charles A Janeway
Jan 8	The Early Recognition and Treatment of War Neuroses and the Common Psychoses	Dr H Houston Merritt
Jan 22	The Acute Abdomen	Dr Hollis L Albright
Feb 19	Chest Injuries	Dr John W Strieder
Mar 5	Vitamins with Special Reference to Surgical Patients	Dr Harold Jeghers
Mar 19	Surgery of the Neck	Dr Herbert D Adams
Apr 2	Genitourinary Infections	Dr Oscar F Cox
Apr 23	Chemotherapy	Dr Howard Allen

CAMP EDWARDS

Nov 23	Hypertension	Dr Laurence B Ellis
Dec 17	Surgery of the Neck	Dr Richard B Cattell
Dec 30	Atypical Pneumonias	Dr Maxwell Finland
Jan 14	Emergency Abdominal Surgery	Dr Samuel F Marshall
Jan 28	Back Pain and Foot Trouble	Dr William A Rogers
Feb 11	Syphilis	Dr Francis M Thurmon
Feb 25	Blood Diseases with Particular Reference to Blood Infections	Dr William Dameshek

Mar 11	Shock	Dr Stanley Bradley
Mar 25	Peripheral Vascular Surgery	Dr Reginald H Smithwick
Apr 8	Head and Spine Injuries	Dr Donald Munro

PORTSMOUTH NAVY YARD		
Dec 17	Pneumonia	Dr Maxwell Finland
WESTOVER FIELD		
Dec 3	The Acute Abdomen	Dr Richard B Cattell
Dec 11	The Problem of Head Injuries and Their Treatment	Dr Donald Munro
Dec 30	Low Back Pain and Foot Trouble	Dr Frank R Ober
Jan 13	The Nature and Treatment of Congestive Heart Failure	Dr Samuel A Levine
Jan 27	Atypical Pneumonias	Dr Chester S Keefer
Feb 10	Genitourinary Infections	Dr Oscar F Cox
Feb 24	Burns	Dr Donald W MacCollum
Mar 10	Internal Fixation of Fractures	Lieut Clarke Staples
Mar 24	Chest Injuries	Dr Richard H Overholt
Apr 7	Blood Transfusions	Dr William Dameshek
May 19	Treatment of Knee Injuries	Dr Frank R Ober

The committee recommends.

That the committee be continued and directed to enlarge its activities so far as practicable

That an invitation be extended to the other New England state medical societies to co-operate in this project and that all medical officers of the Army and Navy in New England be offered postgraduate instruction in some form

That the Massachusetts Medical Society underwrite the expense of this effort

W RICHARD OHLER, *Chairman*

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor**

BENJAMIN CASTLEMAN, M.D., *Acting Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 29271

PRESENTATION OF CASE

A twenty-nine-year-old woman was admitted to the hospital because of back pain and an abdominal mass.

Seven and a half months before entry, one month after the birth of an only child, the patient, when wearing a girdle or when leaning against a solid object, noticed a throbbing sensation in the left lower quadrant, which was synchronous with the pulse. The pregnancy was her first, and was not remarkable except that during the last five days of the puerperium urinary retention was severe and required catheterization. The delivery was at term and was uneventful. Following delivery she suffered with extreme fatigability, her habitual constipation increased and nausea developed. Four months before entry, one week prior to catamenia, a severe aching pain developed in the mid-dorsal region that was intermittent during the day and constant during the night, often interfering with sleep. Before and during this catamenia, which was normal in amount and duration, she had severe abdominal cramps that made her double up. She had never had premenstrual or menstrual distress. Subsequent periods were entirely normal. At that time she felt a small firm nontender mass in the left lower quadrant. Three weeks before entry the mass increased in size and gradually rose higher in the left side of the abdomen. During the three weeks prior to admission the back pain became progressively worse and the patient was obliged to sleep in a sitting position. She gave up the use of proprietary laxatives because of the great exacerbation of pain that these produced. Her physician confirmed the presence of a mass in the left side of the abdomen. At the time of admission she was troubled by weakness and back pain. At no time had there been any menorrhagia, metrorrhagia, hematuria or pyuria. Despite continuous nausea she had vomited only once in eight months. She had never been jaundiced. The stools had never been tarry, bloody or acholic, nor was the urine dark.

*On leave of absence.

There was never any flank pain with radiation to the groin. During the illness she had lost 6 pounds.

The family and past histories were noncontributory. The menarche occurred at fourteen and a half years. The cycle was regular at twenty-six to thirty days, and catamenia lasted four or five days without distress, except as already noted. There was no leukorrhea, and she denied venereal disease.

Physical examination disclosed a well-developed and well-nourished woman. A few small lymph nodes were felt in the left posterior cervical triangle. The heart and lungs were normal. There was no abdominal rigidity or tenderness. A firm, tender mass was felt in the left hypochondrium extending upward somewhat under the costal margin, laterally into the left flank, and downward and medially to the umbilicus. It seemed round, firm and smooth. It moved with respirations and slightly with change in position but had no notch. Fingers could be placed on the superior aspect of the mass, especially when the patient was lying on the right side.

The blood pressure was 138 systolic, 100 diastolic. The temperature was 98°F., the pulse 82, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,900,000, with a hemoglobin of 12.5 gm., and a white-cell count of 6700, with 73 per cent neutrophils, 15 per cent large lymphocytes, 9 per cent small lymphocytes, 2 per cent monocytes and 1 per cent eosinophils. A blood Hinton test was negative. The stools on three examinations were dark brown and guaiac negative.

A flat plate of the abdomen demonstrated a 7-cm., round, soft-tissue mass in the left midabdomen superimposed on the lower pole of the kidney. It showed central radiolucency. No unusual areas of calcification were seen, and an intravenous pyelogram was negative. The left ureter was incompletely filled in the region of the mass. During a barium enema, the barium passed through a normal rectum, colon and cecum. There was no connection between the bowel and the previously described mass.

An exploratory laparotomy was performed on the eighth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS E. ANGLE: May we see the x-ray films?

DR. GEORGE W. HOLMES: There is only one obvious variation from the normal here, and that is the round mass which is described in the text. The colon was negative and in the lateral view the mass lies almost lateral to the vertebral

bodies, well back in the abdomen. The center of the mass is said to be translucent. That may be so, but I should not put much weight on that statement. If one could be sure of that observation I think the tumor would contain fat and would possibly be a dermoid cyst. But the colon overlies it, and the area of decreased density may be gas in the bowel rather than anything in the tumor itself. It would be interesting to determine whether the tumor was attached to the kidney and whether it moved with respiration.

DR. ANGLE: It did move with respiration. The matter of translucency bothered me a good bit.

DR. HOLMES: I should not disagree with that statement about radiolucency; however, I should not want to change my diagnosis on account of it.

DR. ANGLE: The onset of this patient's difficulty one month after delivery of a baby raises the question of whether or not this pregnancy was related to her subsequent difficulty. The only tumor that I can relate to pregnancy is chorion epithelioma, and the usual features of this disease are entirely lacking. It is safe to assume that the pregnancy was coincidental and had no bearing on the later troubles.

We are confronted, then, with a story of a mass in the left upper quadrant that had produced nausea, gradually increasing fatigability, increase in the patient's habitual constipation and a severe dorsal back pain, which was worse when she assumed the dorsal decubitus position and was relieved when she assumed a sitting posture; there was also one episode of crampy abdominal pain associated with catamenia. On examination a firm, round mass was found in the left upper quadrant, which was slightly tender, moved on respiration and had slight lateral mobility. The commonest mass in this location is an enlarged spleen. The physical characteristics of this tumor as described are not those of an enlarged spleen, which usually retains its general contour. I should think the physical findings were consistent with a tumor or cyst of the spleen, but I find it difficult to explain the other symptoms on this basis, and this holds true of the other intraperitoneal tumors that may occur in this area, such as mesenteric and omental cysts and tumors. Moreover, with a negative barium enema we have no evidence that this tumor originated in the large bowel, nor have we any convincing proof that the tumor originated in the small intestine. There is, however, considerable evidence in favor of a retroperitoneal position for this mass. The posterior reference of the pain, the increase in the pain on the assumption of the dorsal decubitus position, and the relief on assuming a sitting posture suggest to me a retroperitoneal mass with

stretching of the posterior peritoneum and stretching or irritation of the celiac plexus by the underlying tumor. The sitting position relaxes these structures. I believe the constant nausea may also be explained as a result of irritation or stretching of the celiac plexus.

The commonest solid retroperitoneal tumors that occur in this area are, first of all, those arising from retroperitoneal lymph nodes, namely, malignant lymphoma of any type. The mention of nodes in the posterior triangle of the left side of the neck suggests the possibility that this may have been a lymphomatous tumor with early generalization of the disease. However, lymph-node masses in the retroperitoneal area are almost invariably fixed and are not likely to show respiratory excursion or radiolucency. The other solid tumors that occur in this area are retroperitoneal lipoma and fibroma and a wide variety of less common tumors, such as those arising from the adrenal glands and rests and a large number of tumors of uncertain origin, some of which arise from fetal rests. Most of these tumors are fixed and unlikely to show respiratory excursions. Furthermore, they are unlikely to exhibit areas of radiolucency.

A wide variety of cystic tumors occur in this area, the commonest of which are the dermoid cysts. Unlike the solid tumors, the cystic ones are apt to show some degree of mobility, and it might be expected that such a cystic mass might show excursion on respiration. In addition to the dermoid cysts there are other cystic tumors, such as those arising from the mesentery of the large and the small bowel, the remains of the wolffian duct, and the lymphatic vessels. Rare cysts of enteric origin also occur, some of which are likely to be radiolucent in whole or in part. Cysts of the tail of the pancreas fulfill some of the requirements that we have to meet to explain this patient's symptoms. A cyst of the tail, unlike other cysts of the pancreas, may be relatively mobile and can show respiratory excursion, but again it is difficult to explain the radiolucency on this basis.

Lastly we have to consider tumors and cysts of the kidney. In spite of the fact that a pyelogram was negative and there was no evidence of intrinsic disturbance of the kidney, a tumor originating in the kidney capsule is entirely consistent with this picture. I refer to the mixed tumor of the kidney, which occasionally contains masses of fat and therefore might explain the central area of translucence. The absence of typical renal pain is a point against such an origin of this mass. However, it is possible for tumors of this type, particularly those originating in the kidney cap-

sule, to produce symptoms chiefly by pressure on and disturbance of contiguous structures without intrinsic disturbance of the kidney. The fact that the urine was not recorded interests me and suggests that something was found in the examination.

DR. TRACY B. MALLORY: It was entirely negative.

DR. ANGLEM: I believe that with tumors occurring in this area, particularly when the symptoms are as bizarre and unusual as those presented by

actually in the mesentery of the small intestine, then I cannot assume that. I think the possible explanation is that this was one of those bizarre enteric cysts with mucous cystic structures, which might contain any sort of filling, possibly necrotic cells that were responsible for the fat necrosis.

DR. MALLORY: How can one tie up this tumor with fat necrosis, Dr. Allen?

DR. ARTHUR W. ALLEN: This was a patient from my service on whom Dr. Robert Linton oper-

FIGURE 1. Photograph of Loop of Small Intestine, Showing Cyst in Mesentery (A) and Chalk-like Granules on Serosa (B).

this patient, it is almost impossible to make a precise diagnosis. All one can say with any degree of certainty is that the patient had a retroperitoneal tumor or cyst of unknown origin. I believe that the most likely diagnosis is mixed tumor of the kidney, with a central fatty area.

DR. MALLORY: Dr. Anglem has given an ingenious solution of this problem. I should like to show what the surgeon saw at operation and ask him to consider the matter further.

A large cystic mass was found in the mesentery of the small bowel, and over the adjoining loops of small bowel were little, bright-yellow, slightly chalky masses that grossly were characteristic of fat necrosis (Fig. 1). The opinion of the surgeon, as well as that of the consulting pathologist who was called to the operating room, was that it was a tumor in the mesentery, with thin chalky deposits characteristic of fat necrosis on the bowel and on the mesentery itself.

DR. ANGLEM: I am afraid that does not tell me very much except to suggest that the origin was in the tail of the pancreas. If this mass was

ated. The first operation consisted in looking at the cyst and removing one of these little nodules for biopsy. Rather at my insistence he reoperated a little while later and was able to remove this mass without damaging too much of the blood supply to the bowel. The question was whether it involved the mesenteric vessels so intimately that it could not be safely removed. It may comfort Dr. Anglem to know that we did not have any idea what this was until after the sections following the removal of the cyst were made.

CLINICAL DIAGNOSIS

Omental cyst.

DR. ANGLEM'S DIAGNOSIS

Retroperitoneal tumor or cyst (? mixed tumor of kidney).

ANATOMICAL DIAGNOSIS

Chylous cyst of mesentery of small intestine.

PATHOLOGICAL DISCUSSION

DR. MALLORY: The answer to the problem is that the "fat necrosis" was not fat necrosis! All these little chalky spots consisted of dilated lymphatics filled with inspissated lipid material; adiposis of all lymphatics was present. The cyst itself contained putty-like grayish material. I think perhaps the radiologist's report of radiolucency was correct. There was nothing to indicate clearly whether this was neoplastic or entirely mechanical from beginning to end. I think it is quite possible that this was simply mechanical plugging of the lacteal system of the small bowel, with subsequent inspissation of fat from the local lymphatics. On the other hand, another possibility is that this was a lymphangiomatous cyst, which, in turn, had caused the lymphatic obstruction. There was no characteristic lesion that we could make out.

DR. ALLEN: But you thought it was probably a chylous cyst at the time?

DR. MALLORY: I still think so, but that does not prove whether or not it was of neoplastic origin.

DR. ALLEN: A chylous cyst in the mesentery has been described. Was there any recognizable epithelial structure?

DR. MALLORY: None whatever.

CASE 29272

PRESENTATION OF CASE

A thirty-seven-year-old man, a jewelry worker, entered the hospital complaining of chills, fever, abdominal pain and jaundice.

Eleven days before entry, after eating a heavy meal, he developed vague, abdominal discomfort. The following day he vomited, and two days later developed pain to the left of the umbilicus, which was relieved by an enema. During the next two days he had almost a constant urge to move his bowels but was able to pass only gas and a little fecal material. During the five days before entry he developed pain to the right of the umbilicus. The pain was cramplike, sharp, occurred at frequent intervals and did not radiate. Six days prior to entry he became jaundiced and his stools became clay colored. Two days later, however, the stools were yellow. During the four days prior to entry, the patient had chills and fever up to 103°F.

The family and past histories were noncontributory.

Physical examination showed a well developed and well nourished jaundiced man. There was dullness with absent breath sounds at both bases posteriorly. The abdomen was slightly distended, with moderate tenderness under the right costal

margin and in the right lower quadrant. There was no spasm. Rectal examination showed large hemorrhoids.

The blood pressure was 140 systolic, 80 diastolic. The temperature was 103.5°F, the pulse 140, and the respirations 40.

Examination of the blood showed a hemoglobin of 12.4 gm per 100 cc and a white cell count of 20,100, with 87 per cent neutrophils. The urine was dark amber in color and gave a ++ test for albumin and a ++ test for bile. The serum bilirubin was 4.1 mg per 100 cc, direct and 5.5 mg, indirect. The prothrombin time was 34 seconds (normal, 22 seconds). The hematocrit was 46.8 per cent. A blood Hinton test was negative. The stools were brown but bile negative.

A portable film of the chest showed a slightly elevated diaphragm on both sides and some atelectasis in the right lower lung field. A film of the abdomen showed a moderate amount of gas in the colon and stomach, but no definitely dilated loops.

For the first three days the fever ranged between 101 and 102°F, and the jaundice remained about the same. The liver was felt below the costal margin, but the abdomen remained unchanged. On the fourth day the abdomen was softer and there was no tenderness or spasm. The patient had some diarrhea; the stools continued to be brown but bile negative, and the urine to contain bile. Diarrhea continued for three days, and a proctoscopic examination showed two or three thrombosed hemorrhoids at the anal margin. The mucous membrane of the rectum appeared normal. Beginning on the fifth day the patient began to have a spiking temperature, ranging from 98 to 104°F each day. On the seventh day there were definite tenderness and resistance in the right upper quadrant, with a suggestion of a mass in this region. A serum bilirubin was 6 mg per 100 cc, direct, and 9 mg, indirect. A blood culture showed no growth. A Widal test was negative.

He was given vitamin K, transfusions and intravenous 5 per cent glucose in saline, but continued to run a spiking temperature with chills; he died on the sixteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. GORDON DONALDSON: In totaling up this patient's illness it is evident that he was sick for nearly a whole month before death. During the last twenty-two of these twenty-seven days he was jaundiced, and from the apparently acholic stools, the bile in the urine, the van den Bergh reactions and, finally, the appearance of a mass in the right upper quadrant, it is fair to say that he was suffer-

ing from an obstructive type of jaundice implicating the extrahepatic biliary system, rather than from a primarily portal type of cirrhosis. It seems unlikely that a diarrhea-producing toxin or chem-

to support the diagnosis of cancer of the bowel with metastases to the periportal lymph nodes or even to the liver itself. The onset of symptoms was much too fulminating and severe, and on entry

FIGURE 1. *Photograph of Liver, Showing Pylephlebitis and Multiple Abscesses.*

The arrow points to a thrombus in main portal vein.

ical could have so completely and suddenly eliminated bile secretion. So we shall say that he did have an extrahepatic biliary block.

There are, however, features in this story that direct attention to the remainder of the abdomen. The onset of pain was to the left of the umbilicus. Later it settled in the right abdomen, still at umbilical level. Moreover, the patient suffered recurrent diarrhea and occasional rectal tenesmus. Certainly the bowel itself was involved in this process. Typhoid fever can be ruled out by the white-cell count and the solitary negative Widal test. There are no stool cultures or examinations to lead us to implicate the other bacillary and amebic dysenteries. Any of these might have resulted in a primary dehydrating diarrhea and a later liver abscess, which obstructed the flow of bile and produced jaundice. Proctoscopy at such an early stage in the disease need not be positive, but in this case the negative findings probably help to rule out dysentery as a probable diagnosis. *Ascaris* infection, echinococcal disease and Weil's disease should be mentioned in passing as rare but unlikely possibilities. Likewise there is little

the patient is described as a young man in a state of good nutrition.

Subacute gallstone ileus could fit the bowel picture well. The passage of a foreign body through the small bowel would stimulate diarrhea and allow for a shift of the pain about the umbilicus. Moreover, it is described as cramplike, sharp and occurring at regular intervals, which is perfectly consistent with an obstructive, peristaltic type of pain, with the obstruction finally lodging in the terminal ileum. The abdominal film is of no help as no stones were seen, and any small-bowel dilatation would have been minimal in this type of obstruction. A spot x-ray film centered over the gall bladder might have been of real value in revealing stones. Certainly the events in the right upper quadrant were perfectly consistent with common-duct obstruction, perhaps caused by a second gallstone.

It is a little distressing to find that, in spite of all his fever and leukocytosis, there was never any striking tenderness or spasm in the right upper quadrant, at least until shortly before death. However, a deep-seated, thickened, sclerosed gall

bladder might still be inflamed and give little surface indication of its status. It is not uncommon for such an acute or subacute gall bladder by its very juxtaposition to the colon to give diarrhea

tion and jaundice. Acute cholecystitis itself may have caused common duct obstruction, but one would not expect the process to have been complete. The resulting cholangitis persisted. Mean-

FIGURE 2 Roentgenogram of the Upper Abdomen after the Injection of Thorotrast

Note the areas of decreased density (black) representing abscesses in the enlarged liver which has elsewhere taken up the Thorotrast to produce increased density (white). The spleen (arrows) which has uniformly taken up the Thorotrast is homogeneously dense.

and even tenesmus. The degree of bowel symptoms as given in the case history is certainly extreme. As for the locus of pain, it has been said that the gall bladder can give pain anywhere in the abdomen oftener and more atypically than any other organ.

The degree of cholangitis must have been marked, consistent with a complete mechanical biliary obstruction. The severe chills, spiking temperature and white cell count of 20,100 are to be expected in inflammation of the bile ducts. The early abnormal prothrombin time is perhaps more prolonged than one would expect in such an acute process, but still entirely possible.

The initial episode of vague abdominal discomfort followed by vomiting probably marked the onset of inflammation in the gall bladder. Irritation of the colon followed. A stone, which may have been passed at that time or may have already been in the common duct, caused obstruc-

tion while other stones obstructed the bladder, aggravating the inflammatory process and leading to a palpable acute gall bladder or, more likely, to a palpable pericholecystic abscess. Probably at no time was the patient considered to be in good enough shape to allow surgical drainage, and he finally died of his infection and liver failure.

DR DWIGHT L. SISCOE. When one knows all the facts it is difficult to discuss the case without bias. Dr Donaldson has analyzed this patient's illness extremely well, especially the latter part of it. He would have achieved even greater accuracy if he had given more consideration to the onset of the illness, although the protocol perhaps does not emphasize some of the facts that stand out in my memory.

When I first saw the patient, three days after admission, I was impressed by the fact that he was a perfectly well, thirty-seven-year-old man, without antecedent history suggestive of disease,

who, a few hours after eating a large meal, developed nausea and vomiting followed in three or four hours by severe pain in the region of the splenic flexure, diarrhea and fever. This was associated with a constant urge to defecate and was relieved by an enema. Later,—we are told five days before entry, but it was actually twenty-four hours later,—he developed pain to the right of the umbilicus. This pain was constant and sharp, occurred at frequent intervals and did not radiate. Jaundice was not noted until six days after the onset. As Dr. Donaldson stated, these facts certainly implicate the intestines, and this is just the point that I think should be emphasized. It seemed to me that this was typical appendicitis, and we must not allow ourselves to be led astray by the fact that the original pain was on the left side of the abdomen. Diverticulitis and ulcerative colitis were considered and were the reason for proctoscopy.

DR. RICHARD H. SWEET: When I saw this patient he was quite ill, febrile and jaundiced, with a palpable slightly tender liver. There was generalized distention of the abdomen, but no signs of peritonitis. It was obvious from the clinical standpoint that he had pylephlebitis of the liver, but by that time there remained no localized signs of the original inflammatory focus from which it arose. All we had to go on were the history and the observations of the family doctor, who is an excellent observer. The latter reported that the tenderness and pain had been confined to the left lower quadrant. Because of that, although acute appendicitis is by far the most frequent source, I made the suggestion that the point of origin might have been a diverticulitis of the sigmoid.

CLINICAL DIAGNOSES

Appendiceal abscess?
Diverticulitis?
Pylephlebitis.

DR. DONALDSON'S DIAGNOSES.

Subacute cholecystitis.
Choledocholithiasis.
Cholangitis, intrahepatic.

ANATOMICAL DIAGNOSES

Appendiceal abscess.
Pylephlebitis.
Multiple liver abscesses.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The post-mortem examination revealed that the primary infection was in the appendix, which formed the base of a large abscess about 9 cm. in diameter. The appendiceal vein could not be identified, but the ileocolic vein was filled with pus and the phlegmon had extended into the portal vein, resulting in widespread intrahepatic pylephlebitis with multiple liver abscesses (Fig. 1). Although the bladder did have a few small stones and mildly inflamed there was no cholangitis and certainly was not a factor in the pathogenesis of the pylephlebitis.

The widespread distribution of the liver abscesses had been determined before death by intravenous injection of Thorotrast (Fig. 2), which proved that surgical drainage would have been futile. Occasionally, when there is one large abscess or one cluster of small abscesses, drainage may be attempted.

JAUNDICE FROM HUMAN SERUM

EVER since immunization against yellow fever has been undertaken on a large scale there have been reports of jaundice of varying severity occurring in inoculated persons. In the early reports attempts were made to explain the occurrence of such cases on the basis either of coexisting epidemics of catarrhal jaundice or of actual infections with living yellow fever virus contained in the vaccine. These explanations have since been discarded as not entirely fitting the facts.

In 1939 about 1,300,000 persons received protective inoculations against yellow fever. One hundred and eighty seven different lots of vaccine were

involved, but in each the virus had been preserved in human serum. One lot alone gave rise to jaundice in 304 persons, or slightly more than one fourth of those to whom it was given. A change made in the seed virus seemed to eliminate the difficulty, but in 1940 many cases again appeared following the use of other lots of vaccine.

With the mobilization of troops for service in yellow-fever areas, vaccination against this disease was undertaken on a large scale among the armed forces, and during the first six months of 1942 over 25,000 cases of jaundice appeared among American troops who had received such protective immunization. There were 62 deaths, making a case fatality rate of about 0.25 per cent. The vaccine used in all these cases likewise contained human serum as a base.

More recently a change to a vaccine with an aqueous base seems to have eliminated this complication, without impairment of the immunizing qualities of the vaccine, as indicated by laboratory tests. Over six hundred thousand doses of this aqueous base vaccine prepared by the United States Public Health Service have now been used, and no untoward effects have been recorded after an apparently adequate period of observation.¹

In Great Britain, cases have been encountered in which jaundice and the other symptoms characteristic of the syndrome following the inoculation of yellow fever vaccine occurred after the injection of human serums that did not contain yellow-fever virus. Medical officers of the British Ministry of Health have recently prepared a thought provoking review of the present knowledge and recent experiences in this field, under the title "Homologous Serum Jaundice." A few of the outbreaks noted in this report, other than those following yellow-fever vaccine, deserve brief mention.

The earliest cases date back to 1885, when 191 cases of jaundice occurred in Bremen several weeks after vaccination of 1289 shipyard workers with a "glycerinated humanized lymph." In two groups of workers in the same shipyard who were vaccinated at the same time with different batches of lymph, no jaundice occurred.

In 1937, an outbreak occurred in which 41 out of 109 recipients of a single batch of measles convalescent serum given subcutaneously developed jaundice, and 8 of them died. These cases were scattered through the southern part of England. In addition, 11 cases of jaundice were reported following the injection of pooled Berkefeld-filtered measles adult serum, with 1 death.

In March, 1942, of 266 British troops who each received less than 14 cc. of Seitz-filtered mumps convalescent plasma in one or two doses intravenously, 86 developed jaundice. Furthermore, 48 cases of jaundice following the injection of mumps convalescent serum were studied at the Harvard-Red Cross Hospital.

In Great Britain, about a dozen cases have also been reported in which jaundice occurred after a long interval following the last of a series of transfusions of large amounts of dried and reconstituted human serum. And, cases following repeated whole-blood transfusions have been noted.

In this country, Beeson³ has reported 7 cases of jaundice that occurred from one to four months after transfusions of blood or plasma given at the time of injuries or of surgical operations. Three of these cases were recent, and 4 were culled from the records of 79 cases at the Grady Hospital in Atlanta in which the patients had been diagnosed as suffering from acute catarrhal jaundice or toxic hepatitis. Clinically these cases were similar to the mild cases of jaundice in the groups already mentioned.

Jaundice was the outstanding clinical feature in all these cases, and varied in severity. In the fatal cases, there was a fulminating hepatic necrosis, and widespread changes in other organs. Splenic enlargement was inconstant. Urticarial and other rashes, usually classed as erythema multiforme, occurred in almost half the cases. Stiff joints without swelling occurred in about one fourth of them. There was some itching before the onset of jaundice. Anorexia, nausea and a heavy feeling in the epigastrium were the other frequent symptoms. The latent period between injection and symptoms

was usually between sixty and ninety days, ranged from two to eighty weeks.

Analogous conditions have apparently been countered in horses after the injection of homologous immune serums prepared in other horses but not with serums prepared in other animals; hence the designation "homologous serum jaundice."

In the cases of jaundice in human beings, factors in the serum responsible for this condition have not yet been identified. Data concerning donors are difficult to obtain in retrospect, and records are incomplete. Furthermore, the incidence and the occurrence of this complication are difficult to determine because of the long incubation period. This makes it highly essential to keep complete records concerning the donors and recipients of all preparations made from human blood. In the past it has been necessary to inquire concerning drugs and other toxic agents in all cases that might be classed as catarrhal jaundice or toxic hepatitis. Now it is also necessary to consider previous inoculations as a possible cause of the jaundice in such cases. Only in this way can we hope to obtain further information regarding this extremely interesting and baffling condition that may be useful both in its prevention and in its management.

NEW TREATMENT FOR THE "HOOPING COUGH"

WILLIAM Moss, of Liverpool, writing about 1784 in *The Liverpool Guide*, made the following shrewd remarks concerning the treatment of the chin-cough, known variously as "hooping cough," "whooping cough" and plain "pertussis": "When the complaint takes a favorable turn it is frequently attributed to the means that were last used: hence that means is ever after recorded as infallible. As

it is a disease of the spasmodic or convulsive kind it has been sometimes relieved, or even removed, by a shock or sudden fright: thus riding upon a bear (a frightful mode of travelling no doubt) from the fright it occasions has been said to be serviceable. Giving the patient a part of some disgusting animal, as a mouse, &c., to eat, and afterwards informing him of it; and so forth."

The diversity of the methods of treating whooping cough offers the best evidence of the intractability of the infection and the uncertainty of its course. The drugs that have been used for its alleviation are legion: garlic has been put in the shoes of its victims; they have been taken to the gas works to inhale the invigorating chlorine fumes, they have been treated by x rays, have been injected with serums, vaccines and undenatured bacterial antigens and have received topical applications to the upper reaches of the nasal mucosa. To Osler has been attributed the one form of therapy that has been proof against time—six weeks and a good big bottle of paregoric.

Practically every form of treatment that has been used has been apparently effective in a sufficient number of cases to attract a certain number of adherents, for even whooping cough must some time come to its conclusion; any sedative form of treatment is certain to be palliative to some degree, although none can claim consistently spectacular results. The Sauer type of vaccine given in large doses can be considered as prophylactically successful.

The December 26, 1942, issue of the *British Medical Journal* makes editorial comment, under the title "High Flying for Whoopers," on one of the newer and more novel forms of treatment, as developed and published by the Berne school of medical practice. By this method of treatment, whoopers in scientifically impressive numbers were given ninety minute airplane flights, ascending not too rapidly to an altitude of eleven to twelve thousand feet, which was maintained for forty minutes. An abrupt cure was registered for 22.8 per cent, with another 32 per cent cured within eight days. A

second flight was sometimes necessary. Less spectacular, the Jungfrau was ascended by rail by another group, with no benefit accruing. Truly impressive results, however, were obtained by placing patients in a low pressure chamber for thirty minutes, there being 31 per cent of immediate cures, with an additional 50 per cent improved.

If these results can be consistently obtained something of real value has been offered—provided enough low-pressure chambers can be made available when the need for them arises.

MEDICAL EPONYM

WILLIAMS'S TRACHEAL TONE

This physical sign was described by Dr Charles J. B. Williams (1805-1889) in the fifteenth of a series of lectures delivered to the students of St. George's Hospital, London, during 1836 and 1837. The lectures were published in the *London Medical Gazette* and in book form, both in London and Philadelphia, in 1838 and 1839. The following is a quotation from page 148 of *Lectures on the Physiology and Diseases of the Chest* (Philadelphia, 1839):

in dilated bronchi, if any dullness exist, it is generally in the mammary, lateral or scapular regions of the chest, and is often accompanied by a sound of a peculiar kind. This is a hollow tube-like sound, and from its semblance to that produced by mediate percussion on the trachea, or by tapping with the finger on the mouth of a small phial, I have given it the name of *tracheal* or *amphoric*. I can give you a notion of the kind of sound, by filling up a finger pressed on the larynx or trachea, or on the cheek when the mouth is opened in the manner of sounding the letter O.

In the sixteenth lecture, page 161, Dr Williams mentions the occurrence of the same sound in certain cases above the dullness due to pleural effusion.

Let this portion of lung be perfectly condensed by a liquid effusion, or perfectly consolidated by hepatization, and you will then get the bottle note of the tubes, just as you do of the windpipe where no lung intervenes. But since my attention has been drawn to it, I have met with several cases of both pleurisy and pneumonia in which it existed in a smaller degree, and I had occasion to notice in the last lecture that it sometimes occurs with dilated bronchi.

R. W. B.

ficer it should be of equally great value to the industrial and orthopedic surgeon engaged in civil practice.

The manual is divided into four major sections: united fractures; injuries of the spinal column; compound fractures; and osteomyelitis. The text is well written, and the procedures advocated are clearly described. Adequate warning is given of complications and of the dangers to be avoided. Whereas undue emphasis is given at times to the favorite method of treatment of the surgeon who has written each chapter, the general directions are sound and are stated in a simple understandable manner.

This is an excellent manual, well conceived and ably written. Although it will not make orthopedic surgeons of the medical officers who first treat these injuries, it should lead to greatly improved care, to a rapid return of function and to a great decrease in permanent disability.

First Aid and Bandaging. By Arthur D. Belilios, M.B., B.S. (Lond.), D.P.H. (Eng.), and others. 16°, cloth, 628 pp., with 239 illustrations. Baltimore: The Williams and Wilkins Company, 1942. \$1.75.

This handbook gives a comprehensive exposition of its subject, from the general principles of first aid through all the special sections that are necessary in any consideration of this subject. It even takes up the subject of first aid in maternity cases. The section on the treatment of hemorrhage is clearly and soundly given so that a first-aid student can easily grasp the situation.

The three chapters on the respiratory system, resuscitation and asphyxia are well illustrated and much to the point. In the section on burns, the question of shock and excluding air from the burned surface, the removal of clothing and absolute cleanliness are given the importance that they deserve. As in so many first-aid books, immediate treatment with a solution of sodium bicarbonate is given prominence. It is of interest to read that the well-known, earlier treatments with carron oil and with various ointments are only mentioned as having now been discarded, at least in all but the most trivial burns. The triple-dye treatment is given prominence.

The following apt quotation is taken from the first section of the book: "First aid cannot be learned entirely from a textbook, nor can it be practiced by rule of thumb. The layman who attempts to do without professional assistance is not practicing true first aid." Certainly the student of first aid will learn from this book that overzealousness may result in harm to the patient in attempting too much too quickly.

Shock: Its dynamics, occurrence and management. By Virgil H. Moon, M.Sc., M.D. 8°, cloth, 324 pp., with 36 illustrations. Philadelphia: Lea and Febiger, 1942. \$4.50.

The basis for this text may be stated briefly as follows: Shock results from leakage through capillary walls, not only at sites of injury but throughout the body, particularly in the viscera. The resulting decrease in effective circulating plasma volume causes tissue anoxia and therefore death. If there is no local trauma, capillary leakage is assumed to result from various deleterious agents affecting the capillary walls directly or as a result of the anoxia caused by such agents. The evidence for capillary leakage is the presence of congestion of the peripheral vessels, petechial hemorrhages, edema and effusions, which are uniformly present in all types of shock. Since hemoconcentration is an inevitable sequel, it is always present.

Such phenomena will not be found in hemorrhage, because hemorrhage is not shock.

The data are woven into a pattern that results in a reaffirmation of the classic view of shock. The author, however, has found it desirable to redefine shock as follows: "Shock is a disorder of fluid balance resulting in a peripheral circulatory deficiency which is manifested by a decreased volume of blood, reduced volume flow, hemoconcentration, and by renal functional deficiency." No doubt this definition will require alteration in the light of the enormous mass of new data that are now being gathered. For example, there is recent evidence contradicting the theory of leakage through capillaries outside local areas of injury. The kidney, furthermore, although a vital organ, is no more important than the liver, the function of which has also been shown to fail.

The reviewer believes that much of the evidence cited in support of the author's viewpoint is too selective, and some of it insufficient in detail, to be convincing. The case histories in support of the evidence for hemoconcentration (pp. 249-251) are an illustration in point. So far as the pathological data on leakage are concerned, the presence of congestion and petechial hemorrhages does not necessarily imply the existence of increased capillary permeability.

A number of statements are of dubious validity. Examples of such statements are the following: Page 24—"[Among the clinical signs of shock] there is a constant thirst but efforts to relieve it are ineffectual because of persistent vomiting. . . . Often there is diarrhea. . . ." Page 50—"If arterial vasoconstriction were an important primary factor initiating shock, one would expect that syndrome to develop occasionally in cases of so-called essential hypertension. . . . An extensive superficial burn will result in shock in a degree proportional to the severity and the area of the burn. If treated promptly, as with tannic acid, shock may not develop or will be of lesser degree." Page 126—"In one group of experiments, a neutralized solution of trypan blue, pH 7.6, was injected intravenously when examinations of the blood indicated that hemoconcentration was developing. Extensive visceral areas were found at necropsy to be stained with the dye. . . . Likewise the serous effusions in the pleural and pericardial cavities were distinctly tinged with blue. The muscles and other peripheral tissues were not affected. *These results indicate that capillary endothelium in extensive visceral areas became abnormally permeable to colloids. The permeability and the loss of fluid were not limited to the area of tissue injury. This finding is incompatible with the belief that shock is due to loss of fluid in local areas of trauma.*"

In the reviewer's opinion, the book is not likely to rank among the enduring contributions to the subject of shock.

A Textbook of Clinical Neurology, with an Introduction to the History of Neurology. By Israel S. Wechsler, M.D. Fifth edition. 8°, cloth, 840 pp., with 162 illustrations. Philadelphia and London: W. B. Saunders Company, 1943. \$7.50.

Four editions of this popular textbook have been called for since it was originally issued in 1927. Since the last edition, four years ago, new material has been added regarding chemotherapy, headache, electroencephalography and a few other topics. The book is therefore improved and its usefulness enhanced.

NUMBER 3

THIOURACIL IN THE TREATMENT OF THYROTOXICOSIS*

ROBERT H. WILLIAMS, M.D.,† AND GROSVENOR W. BISSILL, M.D.‡

BOSTON

A FEW cases of thyrotoxicosis must of necessity be treated by nonsurgical methods, and in some other cases such methods are preferable. Whether one can expect to treat most of the cases effectively by medical means is only conjectural, since the etiology of thyrotoxicosis and all the activities involved in its production are obscure. Thus far, the measures employed in the medical treatment of this condition, although quite effective in some cases, do not work out satisfactorily in the majority. Moreover, it is not known why iodine is effective in some cases and not in others, and its mechanism of action is uncertain. Such a state of ignorance induces one to approach the matter from various angles.

During the last few decades quite a large number of goitrogenous agents have been described. The effect of many of these substances has been attributed to the alterations in the iodine metabolism that they induce, since the simultaneous administration of iodine inhibits the goitrogenous effect. Certain other substances, such as cyanide, presumably induce goiters by inhibiting the biologic oxidation of the body cells. However, there have recently been described^{1,2} certain substances that induce goiter, presumably by their direct action on the thyroid gland. These are the sulfonamides, thiourea and thiourea derivatives. Following their administration to certain animals, particularly rats, thyroid enlargement results in a few days. Histologically, one finds hyperplasia of the acinar cells and a decrease in the colloid of the follicles. A drop in the basal metabolic rate occurs, and after a few weeks may be marked. These changes can be prevented by the administration of desiccated thyroid or thyroxine. They can also be prevented by

hypophysectomy but not by the administration of iodine. In rats fed sulfaguanidine changes in the pituitary glands similar to those following thyroidectomy take place. These facts suggest that the above drugs act directly on the thyroid gland, inhibiting the production of thyroxine, thus in turn leading to a decrease in the body metabolism and to an increased activity of the pituitary gland.

Astwood³ tested the goitrogenous effect of a large number of sulfonamides and derivatives of thiourea. He found 2-thiouracil to be the most active substance tested. He used this substance in the treatment of 3 patients with thyrotoxicosis and found that it lowered the basal metabolic rate and caused a remission of symptoms, but when used for only a month a relapse followed its discontinuance. One of his patients, while receiving 2 gm. of thiouracil daily, developed agranulocytosis. Several patients with nonthyroid conditions treated with thiouracil experienced no drop in the basal metabolic rate.

During the last few months we have been studying some of the pharmacologic and therapeutic effects of thiouracil.[§] In this paper we are considering its effect in the treatment of patients with thyrotoxicosis. We have treated all the patients with this disease whom we could find. All patients treated are included in this report. The case reports are given below, comment on them being confined chiefly to the factors that relate closely to the thyroid gland. In addition to the treatment with thiouracil we have given much attention to the patient's general condition. In most cases we prescribed supplemental amounts of thiamine, niacin, civitamic acid and yeast. Several patients with menopausal symptoms were treated with diethylstilbestrol. All the patients were given sedatives at night. None of them were confined to bed. None of the patients were given iodine, with the exception of one who had syphilitic laryngitis, and in this case the iodine treat-

*From the Thorndike Memorial Laboratory and the Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Instructor in Medicine, Harvard Medical School, assistant physician, Thorndike Memorial Laboratory, and junior physician, Boston City Hospital.

‡Research fellow in medicine, Harvard Medical School, assistant resident in medicine, Thorndike Memorial Laboratory assistant in medicine, Boston City Hospital.

§The thiouracil was supplied by the Lederle Laboratories Incorporated, Pearl River, New York.

ment was not begun until after the basal metabolic rate had reached a minus level. All the thiouracil was given by mouth, usually in doses of 0.2 gm.

CASE REPORTS

CASE 1. V.S. (No. 1950T), a 27-year-old man, was admitted to the hospital on January 14, 1943, chiefly be-

There was a fine tremor of the fingers, tongue and eyelids. The pulse rate was 115 and the blood pressure was 140/70. The heart sounds were loud. A slight gynecomastia was present bilaterally.

On February 18, the basal metabolic rate was +66 per cent and the weight was 143 pounds. The protein-bound iodine of the plasma was greatly elevated (28 microgm per 100 cc.—normal, 4 to 8 microgm). Treatment with

FIGURE 1. Case 1.

Note the rate of excretion of the drug in the urine.

cause of acute pharyngitis and laryngitis, which were treated with sulfadiazine. During the previous 6 months he had lost 40 pounds in weight, had become restless and nervous, and complained of intolerance of hot weather. Diarrhea was not infrequently present. He had also been bothered with palpitation and exertional dyspnea.

On physical examination the patient was apprehensive, restless and excitable. The skin was hot, moist, fine and smooth. No eye signs were present. The thyroid gland was enlarged diffusely to three times its normal size; it was firm and smooth, and a bruit was heard.

thiouracil was started, the dosage being 0.2 gm. three times daily. After 2 days this was increased to 0.2 gm five times daily. Within a few days there was a distinct clinical improvement and the metabolic rate began to fall (Fig. 1). On March 2, the dosage of thiouracil was increased to 0.2 gm. every 4 hours. By March 23, or 5 weeks from the initiation of the thiouracil treatment, the metabolic rate had returned to normal (+3 per cent). The dosage of thiouracil was gradually reduced to 0.2 gm once daily. This dosage has been satisfactory in maintaining the metabolic rate at a normal level.

Associated with the drop in the metabolic rate there was a clinical response of equal degree. All the symptoms of thyrotoxicity disappeared. A definite effect was noticeable a few days after the treatment was started, but the most rapid response was from the 3rd to the 5th

CASE 2. F.D. (No. 1098272), a 55-year-old painter, was admitted on February 27, 1943. The onset of thyrotoxic symptoms occurred 2 years before seeking treatment. The patient lost 24 pounds in weight, became nervous, perspired excessively and was troubled with

FIGURE 2. Case 2.

Note the amount of the drug excreted in the urine.

week. The patient gained 15 pounds in weight within 3 weeks. On May 15, the protein-bound iodine of the plasma was 5.1 microgm. per 100 cc.

During the first few days of treatment there was an increase in the consistence and size of the thyroid gland. Thereafter it became softer than at any time previously and decreased in size, although it was still above normal size. No eye signs of Graves's disease developed.

While the patient was receiving 1 gm. of thioracil daily he excreted about 300 mg. in the urine per day. When the dosage was 1.2 gm., he excreted about 400 mg. per day. Stool specimens saved for a period of 4 days contained no thioracil.

The patient was kept in the hospital for 6 weeks. Three weeks after discharge he was permitted to resume his work.

palpitation and dyspnea. Only slight prominence of the eyes had been noticed.

On physical examination the patient was restless and excitable. The skin was hot, fine and sweaty. A marked tremor of the hands was present. There was slight exophthalmos—each eye measuring 18 mm.—with widening of the palpebral fissures, conjunctival injection, palpebral edema, slight chemosis and lacrimation. The thyroid gland was about three times normal size, firm and slightly nodular. There was slight cardiac enlargement. The pulse was grossly irregular in force and rhythm, having an apical rate of 170 and a radial rate of 110. The blood pressure was 130/70.

On March 2, the basal metabolic rate was +84 per cent, and 2 days later it was +74. On March 4, the patient began receiving 0.2 gm. of thioracil every 4 hours.

He excreted about 350 mg. of this drug per day in the urine. The metabolic rate fell rapidly, reaching a normal rate (-7 per cent) in less than 4 weeks from the beginning of treatment (Fig. 2). On April 7, the protein-bound iodine of the plasma was 1.8 microgm. per 100 cc., which is definitely in the myxedematous range.

Concomitant with the changes in the metabolic rate there occurred a marked clinical improvement. All the symptoms of toxicity disappeared and the patient gained 12 pounds in weight. The auricular fibrillation ceased spontaneously early in the course of treatment. It reappeared but was stopped with quinidine and did not return. The thyroid gland became distinctly softer and somewhat smaller.

The condition of the patient's eyes was followed carefully because it was realized on the first examination that the changes in the eyes, although mild at the time, were of the type that leads to the classic state of so-called "malignant exophthalmos."⁴ After having received thiouracil for 2 weeks, the ocular disturbances became more marked. There was a slight increase in the exophthalmos (measurement, 20 mm.), the lacrimation, the palpebral edema and the chemosis of the conjunctiva. Previous experiences with a large number of patients with this ocular complication⁴ led us to conclude that desiccated thyroid is of advantage in the treatment of this condition. On April 9, after the basal metabolic rate had been maintained in a normal range for 10 days, the patient was given desiccated thyroid, 0.5 gr. per day. At the same time treatment for syphilis of the larynx was started. This consisted of weekly injections of 0.13 gm. of bismuth salicylate and 5 drops of a saturated solution of potassium iodide three times daily. The laryngitis improved rapidly, and there was no thyrotoxicity induced by the iodide, as occurred when Webster and Chesney⁵ gave this substance to rabbits with goiters induced by cabbage. The eyes showed definite improvement, but this was more pronounced when the dosage of thyroid was increased to 1 gr. per day on April 21.

On April 12, 2 days after discharge, there developed swelling and slight tenderness of the submaxillary salivary glands. However, these glands subsided in spite of continued treatment with thiouracil.

The metabolic rate has been normal for the last 6 weeks, and during this time there has been no clinical evidence of thyrotoxicity. The patient has continued taking thiouracil daily, but the dosage has gradually been reduced from 1.2 to 0.4 gm. He is now working regularly as a painter.

CASE 3. K.T. (No. 1099647), a 54-year-old woman, was admitted on March 11, 1943. Onset of thyrotoxic symptoms occurred 1 year before seeking treatment. The first manifestation was nervousness, leading to restlessness, insomnia, frequent crying spells and tremor of the hands. A short time later she began to lose weight, in spite of an increased appetite, having lost 22 pounds within a few weeks. She had no diarrhea. Her eyes developed a stare. She became sensitive to hot weather and perspired excessively. For 6 months she had experienced exertional dyspnea and swelling of the legs, the latter being more marked at night. For 3 months she had been treated by a physician for a toxic goiter, the treatment consisting of rest and large doses of sedatives, but no iodine.

On physical examination the patient was restless and emotionally unstable. The skin was hot, fine, moist and

red. There was a marked tremor of the hands, eyelids and tongue. The eyes had a distinct stare but there was no exophthalmos. The thyroid gland was diffusely enlarged, being about three times normal size. It was firm and smooth in outline, and a distinct bruit was heard. The pulse rate was 105. The blood pressure was 140/75. The heart sounds were rapid and forceful.

On March 12, the basal metabolic rate was $+80$ per cent and the weight was 126 pounds. The protein-bound iodine of the plasma was 21 microgm. per 100 cc. Immediately thereafter the patient began receiving 0.2 gm. of thiouracil every 4 hours. With this dosage she excreted 400 mg. of the drug per day in the urine (Fig. 3). However, stool specimens collected for 4 days contained no thiouracil.

Within $3\frac{1}{2}$ weeks after treatment with the drug was begun, the basal metabolic rate reached a normal range and has remained there during the subsequent 6 weeks that she has been followed. On April 12, the protein-bound iodine of the plasma fell to 5.7 microgm. per 100 cc. The clinical response has been in accord with the changes in the metabolic rate. The patient has gained 13 pounds in weight and all signs of thyrotoxicity have disappeared. The stare is no longer present and no other eye signs have developed. The thyroid gland increased slightly in size during the first few days of treatment. It then began to get smaller and softer, now being about twice normal size. A bruit is still present.

After having taken thiouracil for 3 weeks, in doses of 1.0 to 1.2 gm., the patient developed puffiness of the eyelids and definite edema of the legs. She had had edema of greater degree periodically during the preceding 6 months. On investigating the etiology of the edema no evidence of heart failure was found. The urine was negative; a phenolsulfonephthalein test was normal. The total serum protein was 7.38 gm. per 100 cc. and the nonprotein nitrogen 25 mg. However, the serum chloride was found to be 116 milliequiv. per liter. At the time that the edema appeared the basal metabolic rate was $+1$ per cent and the dosage of thiouracil was 0.2 gm. five times daily. This was reduced to 0.2 gm. three times daily, and within 3 days the edema disappeared and the serum chloride returned to normal, the metabolic rate remaining normal.

The patient was kept in the hospital for 1 month, had restricted activities for the next 2 weeks, and since then has carried out her usual program as a housewife. She is now taking 0.2 gm. of thiouracil per day.

CASE 4. R.L. (No. 1099980), a 49-year-old factory worker, was admitted on March 15, 1943. She had not been well since the first onset of thyrotoxic symptoms 22 years previously. At that time she had three operations for toxic goiter, and following the last operation was told by her surgeon that she should never be operated on again. She experienced a distinct improvement following these operations but never became free of toxic symptoms. The patient, as well as her relatives and friends, had noticed that she always tended to be overactive and restless. The eyes remained prominent and she had had a goiter throughout most of the 22 years. There was a progressive loss of weight and strength until the patient became emaciated. During the year before admission the symptoms of toxicity increased, with further enlargement of the goiter, more pronounced sweating, nervousness, palpitation and weakness. During the few months before hospitalization there was a hacking cough, dyspnea,

orthopnea and transient edema of the legs. She had taken digitalis intermittently during this time. Throughout the 22 years she had periodically taken Lugol's solution, with some improvement in symptoms.

Physical examination revealed a tall, weak, emaciated woman, who was restless, apprehensive and irritable. The

The patient had a great fear of having another thyroidectomy and for this reason was constantly begging to leave the hospital. She refused to consider medical treatment of her toxic goiter because the many years of such treatment had fully convinced her that the condition could not be improved. She detested hearing the

FIGURE 3. Case 3.

Note the rate of excretion of the drug in the urine.

skin was hot, moist, smooth, fine and somewhat loose. Over the elbows and heels it was fiery red, owing to redness in bed. The eyes truly had the appearance of pop eyes, there being a pronounced stare and wide palpebral fissures. The exophthalmos appeared marked, but measurement showed it to be slight (20 mm.). No palpebral edema was present. The tongue was bright red. The neck was long and slender. A goiter was readily visible above the old thyroidectomy scar. There was two to three times the normal amount of thyroid tissue. It was hard and slightly irregular in outline, and a bruit was heard. The pulse was grossly irregular in force and rhythm; its rate was 110. The blood pressure was 120/60. The heart was moderately enlarged and its contractions were forceful. No murmurs were heard. There was slight pitting edema of the legs, and a few varicose veins. A fine tremor of the fingers was present.

name "goiter" or anything pertaining thereto, because, as her sister stated, "It is like scraping an old and painful sore." The patient presented a good picture of a long-term thyrotoxicosis. Although weak and exhausted to the point of having to be supported in walking, she was begging to go back to work.

On March 16, the basal metabolic rate was +56 per cent. A few days later the patient began receiving 0.2 gm. of thiouracil four times daily. After 2 days, since she had not been upset by this medication, the dosage was increased to 0.2 gm. every 4 hours. On this dosage she excreted 250 mg. of the drug per day in her urine (Fig. 4). During the first 2 weeks of treatment she showed only slight improvement. The course was complicated by the development of several corneal ulcers in each eye owing to exposure during sleep. The diet was supplemented with niacin, thiamine, riboflavin, cevitamic

acid and vitamin A. However, the condition of the eyes and the slowness in gaining weight caused her to be somewhat discouraged. In an attempt to break a vicious cycle she was given 10 mg. of methyl testosterone three times daily for 5 days (we hesitated to use larger quantities of this drug since it sometimes causes elevation in

now been reduced to 0.2 gm. three times daily. The patient has been permitted to return to work.

CASE 5. M. R. (No. 1101316), a 35-year-old housewife, was admitted on March 12, 1943. She had been well until 1 year previously, when she became restless, irri-

FIGURE 4. Case 4.
The infrequency of the metabolism tests was due to the patient's refusal to have them run.

the basal metabolic rate).⁶ The methyl testosterone appeared to have improved the patient's strength and mental attitude to a slight extent. After having received treatment with thiouracil for 3 weeks the patient left the hospital, against advice, but carried on her treatment faithfully at home. During the 4th week of this treatment she improved rapidly and continued to do so. By May 11 she had gained 16 pounds in weight and the thyrotoxic state had disappeared. The eyes showed a decrease in stare. The amount of thyroid tissue had not changed much, but the gland was not quite so firm as originally. A distinct improvement in the cardiac status had occurred, but the auricular fibrillation was still present.

The patient so disliked basal-metabolism tests that she would not permit many of them. However, the tests that were run showed essentially a straight-line drop from +58 to +7 per cent. The dosage of thiouracil, which for the most part had been 0.2 gm. five times daily, has

table, excitable and easily upset. Thereafter she experienced insomnia, heat intolerance, diarrhea, a loss of 20 pounds in body weight, slight exophthalmos, fullness in the neck, palpitation and exertional dyspnea. On physical examination the patient was restless, apprehensive and excitable. The skin was hot, moist and smooth and exhibited vitiligo on the dorsum of the hands. There was slight exophthalmos and a small amount of palpebral edema. The thyroid gland was two to three times normal size, slightly irregular in outline and firmer than normal. The pulse rate was 110 and the blood pressure 130/75. The heart sounds were forceful. On March 13, the basal metabolic rate was +45 per cent. On that date the patient began receiving 0.2 gm. of thiouracil five times daily, but only a few hours later left the hospital owing to her anxiety over her six children and her undependable husband. However, she continued the prescribed treatment at home, returning to the hospital at weekly intervals. The metabolic rate progressive-

ly declined reaching a normal level in 6 weeks (Fig 5). It remained normal during the subsequent 3 weeks. With in the same time the protein bound iodine of the plasma fell to a subnormal level (21 microgm per 100 cc). Throughout most of the period of treatment the dosage of the thiouracil was 1 gm daily, but it was gradually reduced to 0.4 gm daily after the metabolic rate had become normal. The clinical improvement exceeded the response in the metabolic rate. Before the latter had become nor-

The basal metabolic rate on April 20 was +88 per cent. The following day treatment with thiouracil was started, the dosage being 0.2 gm every 4 hours. Basal metabolic rates taken at weekly intervals were +55, +9, +18 and +5 per cent. In the meantime a marked clinical response occurred essentially all the signs of toxicity disappeared and the patient gained 6 pounds in weight. She remained in the hospital for only 9 days and since then has carried on her work as a housecleaner.

FIGURE 5 Case 5

nal the signs of thyrotoxicity had disappeared and the thyroid gland had assumed an essentially normal size and consistency. There was a gain of 9 pounds in weight, but this occurred chiefly after the metabolic rate had become normal.

During the 2nd week of treatment the patient developed a very slight macular eruption. The phenobarbital that he had been taking was permanently discontinued and thiouracil was omitted for 1 day. The rash lasted only 2 days and did not recur in spite of the resumption of his usual dosage of thiouracil.

Throughout most of the course of treatment the patient has continued carrying on her household duties.

CASE 6 W F (No 1103790), a 50-year-old Negro woman laborer, was admitted on April 19, 1943. Two years previously she had become nervous, with marked restlessness, excitability and emotional instability. In spite of a normal ingestion of food, she lost 44 pounds of body weight in 2 years. She usually had two bowel movements per day, although sometimes she had five or six. She noticed some puffiness of the eyelids but no exophthalmos. For 2 years she had had a fullness in the neck.

On physical examination the patient was restless, apprehensive and excitable. She cried several times during the examination. The skin was loose but otherwise not remarkable. There was palpebral edema and slight impairment to convergence, but no exophthalmos. The thyroid gland was enlarged to three times normal size, and was nodular and firm. The pulse rate was 96 and the blood pressure 170/80.

The thyroid gland has not shown much change in size but is a little softer. She is now taking 0.2 gm of thiouracil three times daily.

CASE 17 R F (O P D No 434179), a 48-year-old housewife, was first seen on March 29, 1943. She had been somewhat nervous ever since her husband's death 6 years previously. However, she dated the onset of most of her thyrotoxic symptoms to a fire in her home 1 year previously, following which she became distinctly more restless, excitable and hyperkinetic and noticed a tremor, palpitation, exertional dyspnea, a goiter and a stare. She had been losing weight for 4 years but during the past year had done so more rapidly, the total being 50 pounds in the 4 years.

On physical examination the patient was moderately restless and excitable. The skin was hot and slightly moist. There was a stare, lid lag and a slight impairment of convergence, but no exophthalmos or other eye signs. The thyroid gland was about three times normal size, firm and nodular and a bruit was audible. The pulse rate was 100 and the blood pressure 140/75. The basal metabolic rate was +53 per cent.

Hospitalization was advised but the patient had so many duties at home that this could not be arranged. On March 31 she began taking 0.2 gm of thiouracil five times daily. Metabolic rates determined at weekly intervals were +55, +38, +22, +19, +15 and +7 per cent. During this time the clinical response was in accord with the changes in the metabolic rate. All evidence of thyrotoxicity have disappeared. The patient

has gained 9 pounds in weight. The eye signs have disappeared. The thyroid gland has shown a distinct decrease in size and consistence but is not yet entirely normal. On May 12, when the basal metabolic rate was +7 per cent, the dosage of thiouracil was reduced to 0.2 gm. three times daily.

Throughout the course of treatment the patient has carried out her usual housework for a large family.

CASE 8. R.J. (No. 1101981), a 49-year-old Negro woman, was admitted on April 2, 1943. Six years previously she had developed exertional dyspnea. This increased progressively and she found it necessary to sleep on two pillows. Subsequently she developed edema of the legs. Two years previously she became nervous, had three to four bowel movements per day, began to lose weight (a total of 40 pounds), developed swelling in the neck and became sensitive to heat. In July, 1941, she was hospitalized for a myocardial infarction. At that time the blood pressure was 160/90. There was mild congestive heart failure. While in the hospital the patient was found to have thyrotoxicosis with a basal metabolic rate of +31 per cent. She took potassium iodide, with a definite improvement in the clinical state and the metabolic rate. However, after a few weeks she discontinued the iodine and had an exacerbation in her symptoms.

On physical examination the patient was restless, excitable and apprehensive. The skin was moist, warm and fine. There was slight exophthalmos and palpebral edema. The thyroid gland was about three times normal size, firm and nodular. The pulse was rapid. The blood pressure was 190/100. There was slight cardiac enlargement but no congestive failure. The urine contained a small amount of albumin, a few white cells and an occasional red cell.

On April 3, the basal metabolic rate was +55 per cent. Two days later the patient began receiving 0.2 gm. of thiouracil every 4 hours. Examination of the urine showed that she excreted an average of 300 mg. of thiouracil daily during the period of 2 weeks' observation.

The basal metabolic rate at 10-day intervals was +55, +32, +22, +22 and +14 per cent. All symptoms of thyrotoxicity disappeared within 4 weeks. During that time the thyroid gland became definitely smaller and softer. The eye signs were never striking and did not show much change under treatment.

The patient was maintained on a daily dosage of 1 gm. of thiouracil for 5 weeks and the dosage was then reduced to 0.6 gm. daily, given in three doses.

Two weeks after she first began taking thiouracil she developed slight swelling of the legs. Urine examination gave the same findings as on admission and there was no evidence of heart failure. The serum protein was normal, but there were 118 millicquiv. of chloride per liter of serum. The carbon-dioxide combining power was 43 vol. per cent. In spite of continuation of the drug the edema disappeared within a few days and the chloride returned to normal, although the carbon-dioxide combining power remained slightly low (41 vol. per cent). However, the latter had also become normal within 2 weeks.

CASE 9. L.S., a 31-year-old woman, was first seen on March 31, 1943. Three years previously she had developed the manifestations of severe thyrotoxicosis. A thyroidectomy was performed in August, 1941, and another

in October, 1941, followed by a disappearance of the thyrotoxic state. However, 1 year later, during the 2nd month of her seventh pregnancy, the symptoms recurred. She became nervous and intolerant to heat. She noticed an increased prominence of the eyes, swelling of the eyelids, burning and itching in the eyes, tightness in the neck and palpitation. She lost 10 pounds in weight in 6 months, in spite of her pregnancy.

On physical examination the patient appeared only mildly toxic. The skin was slightly moist and hot. The eyes showed slight exophthalmos, with palpebral edema. There was about twice as much thyroid tissue as normal and the gland was of firm consistence. The fingers and tongue had a fine tremor. The pulse rate was 100. The basal metabolic rate was +36 per cent on March 31. On that date treatment was begun, using 0.2 gm. of thiouracil five times daily. She was not admitted to the hospital but came to the Out-Patient Department at weekly intervals. The metabolic rate fell to +27 per cent within a week, remained at that level for 3 weeks and then fell to +12 per cent, which is a normal level for a person 8½ months pregnant.

Clinically, the patient was free of all thyrotoxic symptoms within 3 or 4 weeks. The thyroid gland decreased to almost normal size and became softer. No definite change in the eyes resulted. She is now being maintained on 0.2 gm. of thiouracil three times daily.

DISCUSSION

Absorption, Distribution, Excretion and Dosage

We have found, by the methods of Williams, Kay and Jandorf,⁷ that thiouracil is rapidly absorbed and rapidly excreted. For example, to one normal person we gave 0.2 gm. of thiouracil and collected blood and urine samples at the following times: Fifteen minutes, thirty minutes, hourly through eight hours, two-hourly through twelve hours and twenty-four-hourly through three days. The highest blood level was found at fifteen minutes and was 2.3 mg. per 100 cc. Thereafter it fell rapidly until at eight hours only 0.3 mg. of the drug was present, but it did not entirely disappear from the blood until the third day. The most rapid rate of excretion of the drug in the urine occurred during the second hour, 15 mg. being excreted. Thereafter the rate decreased rapidly, only 12 mg. being excreted during the second twelve-hour period, and a total of 6.3 mg. during the second and third days combined.

When thiouracil is given in doses of 0.2 gm. at four-hour intervals, it requires about twenty-four hours to reach a more or less constant rate of excretion in the urine and a constant blood level. With such dosage the urine excretion is about 300 mg. per day, whereas the blood level is about 3 mg. per cent. When the above dosage has been maintained for several days, thiouracil can be found in the urine for six days or more after discontinuing the drug. When the dosage is 0.2 gm. three or four times daily, about forty-eight

hours is required to attain a more or less constant blood and urine level. Almost all the drug that is in the blood exists in the cells, the concentration in the white cells being many times that in the red cells. However, the latter contain a greater total amount of the drug.

It is obviously difficult to determine the distribution of the drug in the tissues of normal human beings. However, we have studied its distribution in the tissues of 2 patients dying from cerebral hemorrhage and 1 dying from bronchopneumonia. Totals of 1.0 to 3.6 gm. of the drug had been given to these patients. Most of the tissues, including that of the thyroid gland, had from 1 to 3 mg. per 100 gm. (fat-free dry weight). The concentrations in the adrenal glands, bone marrow and pituitary gland were greater than this. We have not been successful in finding thiouracil in any stool specimens.

Although the above studies represent a step forward in the estimation of the most desirable dosage and the intervals at which thiouracil should be administered, many more studies of this type are necessary. It would be particularly worth while to determine the optimum level of saturation of the thyroid gland and the dosage necessary to maintain this level. We are conducting such studies at present.

It is now our policy in the treatment of thyrotoxic patients, in the beginning, to give 0.2 gm. of thiouracil at four-hour intervals five or six times daily. With moderate clinical improvement and a drop in the metabolic rate, we reduce the frequency of medication to three or four times daily, spreading the interval as much as is convenient. After the metabolic rate is normal, we reduce the dosage to 0.2 gm. once or twice daily. Our present impression is that a dosage greater than this is not necessary and that a smaller amount will probably be satisfactory.

It will take some time to ascertain how long thiouracil should be given to a patient. On the basis of experiments with the use of iodine, although in many ways the two substances are incomparable, it seems advisable to give it for many months without discontinuation. Astwood et al.³ found a recurrence of the disease in a patient although the latter had received thiouracil for about two months before it was discontinued.

Mechanism of Action

As indicated above, the data available at present suggest that thiouracil lowers the metabolic rate by inhibiting the formation of thyroxine. In the 4 cases in which we conducted iodine studies, we found that following treatment with thiouracil

for a few weeks the protein-bound iodine* of plasma reached low normal or subnormal levels. Since the amount of thyroxine or thyroxine-like iodine of the blood is presumably an index to the amount of thyroxine produced in the thyroid gland, it seems clear that in some way thiouracil inhibits thyroxine production. However, the exact mechanism by which this is accomplished has not been elucidated.

On the basis of animal experiments,^{1,2} it was concluded that thiouracil did not inhibit the stimulating effect of desiccated thyroid or thyroxine on the metabolic rate. We have investigated this phenomenon in human beings, using thiouracil. Two patients with myxedema were studied. In each case it was established, by methods which need not be mentioned here,⁸ that the myxedema was primary in the thyroid gland. One patient, M.D. (Fig. 6), was found repeatedly to have a basal metabolic rate of about -44 per cent. She was given thiouracil, 1 gm. daily, for ten days, at the end of which time the metabolic rate was -47 per cent. With the continuation of the thiouracil and, in addition, the administration of 1.5 gr. of desiccated thyroid U.S.P. daily, the metabolic rate had risen to -17 per cent after twenty days of the combined treatment. Then with discontinuation of the thiouracil, but continuation of the thyroid, the metabolic rate became -25 per cent. The other patient, B.F. (Fig. 6), was found to have metabolic rates, before any treatment, of -26 and -36 per cent. After she had received thiouracil, 1 gm. daily, for nine days the metabolic rate was -25 per cent. With continuation of the thiouracil and the administration of 2 gr. of desiccated thyroid U.S.P. daily, the rate was -8 per cent. Thiouracil was discontinued for nine days while the thyroid treatment was continued, but no definite effect on the metabolic rate was observed. When thiouracil was again given for thirteen days, it had no effect on the rise of the metabolism induced by desiccated thyroid. Therefore, we may state that thiouracil does not lower the basal metabolic rate of untreated myxedematous patients, nor does it inhibit the response of the metabolic rate to desiccated thyroid.

We conducted an experiment with another patient, M.D. (Fig. 7), to ascertain whether thiouracil inhibits the goitrogenous and hypermetabolic effect of antuitrin T (thyrotropic hormone). The patient selected had been admitted to the hospital because of possible hyperthyroidism. On the basis of clinical grounds, we decided that she did not have a toxic goiter, but we have not completed the

*This is composed of the so-called "D" and "T" iodines, which are essentially equivalent, respectively, to the di-iodotyrosine and thyroxine contents of the plasma.

blood-iodine studies in her case. Particular attention was paid to the changes in the thyroid gland and the metabolic rate, in association with the administration of thiouracil, 1 gm. daily, for a period of twenty-two days. During the first ten

In the 9 cases of thyrotoxicosis reported above, there was a distinct clinical improvement beginning only a few days after the treatment with thiouracil was instituted. This was true whether the patient was hospitalized or was carrying on

FIGURE 6.

Note that thiouracil had essentially no effect in lowering the metabolic rate of two myxedematous patients and that it did not prevent desiccated thyroid from elevating the rate. Also note the rate of excretion of thiouracil in the urine and the duration of its excretion following cessation of treatment.

days the patient was given daily 2 cc. (50 units) of antuitrin T in sesame oil. Within three days after this treatment was begun the thyroid gland had become definitely larger and firmer. Since the enlargement occurred so rapidly, we believe that it was due chiefly to the thyrotropic hormone injected. The metabolic rate not only failed to rise, but actually showed some decline (Fig. 7). Thus it appears that the thyroid gland had been stimulated to become hyperplastic but that its hypermetabolic effects were inhibited. Finally, the effect of thiouracil was tested in a patient, F.C. (Fig. 7), with a large colloid goiter. The drug was given for seventeen days, 1 gm. daily, but it was found to have no effect on the metabolic rate, or the goiter during this period of observation.

Results of Treatment

Although one is interested in observing any and all effects, good or bad, of thiouracil in the treatment of thyrotoxic subjects, most of the attention is centered on the clinical response of the thyrotoxic manifestations, including particularly the amount of gain in weight; the fall in the basal metabolic rate; the changes in the thyroid gland and the changes in the eyes.

essentially his normal amount of work. Of course, the thiamine,⁹ sedatives, reassurance and other such factors played a distinct role in this accomplishment. This improvement increased progressively until the symptoms of thyrotoxicity had essentially disappeared, within four to seven weeks. Gain in weight, a good index to improvement, took place, most rapidly during the fourth and fifth weeks of treatment.

The fall in the metabolic rate was in close accord with the clinical improvement. In almost all cases the metabolic rate did not fluctuate, but fell progressively downward, in some cases going as low as -15 per cent. A normal level was reached as quickly in severe cases as in the milder ones. Once it returned to normal it tended to stay there so long as the thiouracil was continued.

The changes in the thyroid gland were variable. In 3 patients there was definite, but slight, enlargement in the gland during the first two weeks of treatment. Subsequently the glands returned to their original size. In 2 cases the gland became progressively smaller and softer, finally returning to an essentially normal size. In the other 4 cases it became somewhat smaller and softer than it was originally. In this connection it is significant

that in Case 2 the gland became definitely smaller and softer in association with treatment with desiccated thyroid.¹⁰ This method of treatment has a good rationale because it tends to inhibit the excessive production of thyrotropic hormone, thus

A second possible complication consists of renal involvement. Thiouracil is quite insoluble in distilled or tap water, although it is readily soluble at pH 8.5. We have found no crystals in the urine, no albuminuria and no sedimentary changes.

FIGURE 7.

Note that antuitrin-T (thyrotropic hormone) administered with thiouracil caused no elevation in the metabolic rate of a "normal" subject (M.D.). Note also that the treatment of a patient with a large colloid goiter (F.C.) caused no essential change in the metabolic rate. The rate of excretion of thiouracil in the urine should also be observed.

preventing thyroid hyperplasia. We believe that it is partially through this mechanism that desiccated thyroid is of advantage in controlling malignant exophthalmos.⁴ For these reasons, we plan to use thyroid, along with thiouracil, after the metabolic rate has remained within a normal range for a few weeks.

The enlargement of the thyroid gland, associated with thiouracil treatment, that occurred in the 3 cases mentioned above, and the increase in the ophthalmopathy in 1, suggest that in human beings, as in animals, thiouracil leads to excess thyrotropic hormone activity.

Complications of Treatment

The most serious complication thus far observed was the agranulocytosis in a case reported by Astwood. However, his patient was receiving 2 gm. of thiouracil daily, a dosage that is now believed to be unnecessarily high. Yet this is a complication that one must bear in mind, even if a smaller dosage is used, because we have found that the bone marrow takes out a relatively high concentration of thiouracil. We made frequent white-cell counts in our cases, but observed no significant drop.

We have found no essential alteration in the daily urine volume nor in the phenolsulfonephthalein excretion. However, 2 patients developed slight pitting edema with elevation in the serum chloride and a slight fall in the carbon-dioxide combining power. These changes disappeared without discontinuation of the drug and apparently led to no ill effects. Nevertheless, the mechanism of the development of these changes is being investigated.

One patient developed swelling and slight tenderness of the submaxillary salivary glands, which subsided after two days in spite of continuation of the drug therapy. There were no complaints of unpleasantness from the taste of the medicine or general effects from it.

In the patient who was pregnant no ill effects were observed. Furthermore, we have found in rats that saturation of these animals with thiouracil did not interfere with the follicularization or the luteinization induced by pregnancy urine.

SUMMARY

Nine unselected cases of thyrotoxicosis have been treated with thiouracil. In each case the

toxic manifestations disappeared and the basal metabolic rate returned to a normal range. Blood-iodine studies, conducted on 4 patients, showed in each case a fall of the protein-bound iodine to a low normal or subnormal level.

Studies have been performed of the blood levels of thiouracil and its excretion in the urine.

No serious complications from the drug have been encountered, but all patients receiving this drug should be carefully followed.

This report deals only with the early changes resulting from treatment with thiouracil. The results of prolonged treatment will be reported at a later date.

SPINA BIFIDA AND CRANIUM BIFIDUM*

V. The Arnold-Chiari Malformation: A study of 20 cases

FRANC D. INGRAHAM, M.D.,† AND H. WILLIAM SCOTT, JR., M.D.‡

BOSTON

THE Arnold-Chiari malformation is a congenital anomaly of the hindbrain characterized by a downward elongation of the cerebellum and brain stem into the cervical portion of the bony spinal canal. The condition has been considered a rarity and is unknown to a large percentage of the medical profession. The purpose of this study is to present evidence that it is a frequent accompaniment of myelomeningocele and to discuss the clinical and pathological significance of this relation and other associated findings.

REVIEW OF LITERATURE

The literature on the malformation is limited. The anomaly was originally described by Arnold¹ in 1894 and by Chiari² in 1895. Schwalbe and Gredig³ published an anatomic and embryologic description of it in 1907, including reference to an earlier study by Solovtsoff.⁴

In 1935, Russell and Donald⁵ reported 10 cases of Arnold-Chiari malformation occurring in infants with myelomeningocele. They showed that the anomaly of the cerebellum and medulla in these cases was the prime factor in the production of the complicating hydrocephalus, and suggested that this anomaly might be the mechanism of hydrocephalus in all cases of myelomeningocele and in some cases of simple meningocele.

Penfield and Coburn⁶ in 1938 presented an attractive explanation of the development of the malformation in a case of theirs observed at operation and autopsy. They considered the malformation to be brought about by traction on the brain stem in embryonic life resulting from fixation of the spinal cord at the meningocele site. Normally, growth of the vertebral column and spinal cord occurs at an equal rate until the third month of intrauterine life. After this the bony vertebral canal outstrips the cord in growth, and owing to the anchoring of the cerebrospinal axis by the position of the cerebellum above the foramen magnum, the spinal cord is normally pulled upward so that the conus medullaris comes to lie opposite the first lumbar vertebra. When spina bifida and meningocele are present, the cord may become fixed by herniation and adhesion at the site of the defect so that traction is exerted on the brain stem by the continued growth of the vertebral column and a portion of the hindbrain drawn downward through the foramen magnum. In support of this theory is the observation of Penfield and Coburn that the cerebellar "tails" retracted upward a distance of 3 cm. on being freed from their attachments to the medulla at operation. In their case, and in those of Russell and Donald, the spinal nerve roots in the cervical region were found to pass upward to the intervertebral foramina, rather than horizontally. This was interpreted as additional evidence of a downward traction on the cerebrospinal axis.

‡Assistant resident in surgery, Children's Hospital and assistant in surgery, Harvard Medical School.

In 1938, Aring⁷ reported a case of cerebellar and brain stem malformation in an adult with cerebellar symptoms without associated hydrocephalus or meningocele. This resembled the Arnold-Chiari malformation anatomically.

McConnell and Parker⁸ in 1938 published a report of 5 cases of hindbrain malformation similar to that described by Arnold and Chiari, but apparently not associated with spina bifida or meningocele. These cases, and that of Aring, tend

ciated with myelomeningocele. The other case was similar to those of McConnell and Parker, and x ray films of the entire spine failed to show spina bifida.

In 1941, List¹¹ included the Arnold-Chiari malformation in an extensive discussion of the neurologic syndromes accompanying bony developmental defects in the occipital region.

Ogryzlo¹² presented 7 cases in 1942. Of these, 3 were associated with myelomeningoceles, and 1

to cast doubt on the traction theory of the genesis of hindbrain malformation, or else suggest that other mechanisms than traction may be concerned in its production. It is interesting that, in Aring's case and in 4 of the 5 cases of McConnell and Parker, spina bifida occulta was not excluded. X-ray photographs of the spine were apparently taken in only 1 case and in that one only the lumbar spine was studied and found normal.

In this same report McConnell and Parker described autopsies on 6 infants with myelomeningocele, 4 of whom had the Arnold-Chiari malformation. In the other 2 there was a "prolongation of flattened cerebellar tonsils through the foramen magnum associated with a nodule on the dorsal surface of the medulla."

D'Ernico⁹ in 1939 discussed the surgical treatment of hydrocephalus associated with spina bifida and emphasized the importance of the Arnold-Chiari malformation in the production of hydrocephalus in such cases. He reported 10 cases of myelomeningocele, all of which had an associated Arnold-Chiari malformation.

Two cases were reported by Adams, Schatzki and Scoville¹⁰ in 1941. One of these was asso-

with simple meningocele, whereas the remaining 3 had no overt spina bifida. Again spina bifida occulta was apparently not excluded.

REPORTED CASES

Twenty consecutive cases of Arnold-Chiari malformation that came under observation at the Children's Hospital from 1929 to 1943 were examined. Nineteen of these were studied at autopsy as well as clinically. Their principal clinical and anatomical features are presented in Table 1. All these patients were infants between two days and eighteen months of age. Meningocele, with or without hydrocephalus, was the reason for hospitalization in each case.

The malformation of the cerebellum and medulla in these 20 cases was anatomically identical with Arnold's original case and with those of Russell and Donald. Two parallel tongue like processes from the inferior poles of the cerebellar hemispheres extended downward through the foramen magnum and were closely applied to the posterior surface of the medulla (Fig 1). In each case from one half to two thirds of the medulla lay below the level of the foramen magnum. The

medulla was somewhat elongated, slightly narrower than usual and flattened anteroposteriorly.

As pointed out by Russell and Donald, the cerebellum was hypoplastic and in most cases lacked differentiation into vermis and lateral lobes. The tail-like prolongations seemed to originate from

FIGURE 1. *Sagittal Section through the Cerebellum and Brain Stem in a Typical Case of Arnold-Chiari Malformation.*

the whole inferior pole of the cerebellum, and in sagittal section appeared to pass down from the nodulus. Microscopic examination of the cerebellar tails shows simply hypoplastic tissue with preservation of the usual cortical architecture.

The fourth ventricle was elongated and flattened. Its lumen was almost obliterated in many cases by the close approximation of the cerebellar "tongue" to the posterior medulla. The foramina of Magendie and Luschka lay below the level of the foramen magnum and were usually identified with difficulty.

In 2 of the cases there was a nodule on the dorsal surface of the medulla, located in the midline and lying just ventral to the lower extremities of the tail-like cerebellar prolongations, or immediately caudal to these. Sagittal sections through

the medulla at this point showed this nodule to represent an exaggeration of the normal structural relations of the most caudal extremity of the fourth ventricle, with an overlapping of the upper cervical cord segment by the adjacent medulla.

The choroid plexus lay in the midline on the ventral surface of the cerebellar prolongations, as a rule, and extended down to their caudal ends. The pia-arachnoid was thickened and extremely vascular over the cerebellar tails, and tended to obscure them in the undissected specimen.

The upper cervical nerve roots were found to run upward to the intervertebral foramina in these cases, just as in those of Russell and Donald and that of Penfield and Coburn (Fig. 2).

Myelomeningocele

Spina bifida and myelomeningocele were present in each of the 20 cases of Arnold-Chiari malformation examined. Usually these were large herniations with extensive neural involvement. In the few that were dissected out post mortem and in all these excised ante mortem there were dense fibrous adhesions binding the lumbar myelomeningocele sac to the margins of the defect in the vertebral arches. Frequently the lumbar nerve roots were incorporated in these adhesions.

Hydrocephalus

Internal hydrocephalus was present in each of the 20 cases of hind-brain malformation. Twelve cases were of the communicating type. In 4 there was obliteration of the fourth ventricle by squeezing of the medulla and cerebellar tails into the narrow confines of the cervical spinal canal. In the remaining 4 cases the type of obstruction was not determined post mortem and no definite conclusion could be reached by re-examination of the fixed brain.

From the work of Russell and Donald and from the examination of the brains in this series it appears that hydrocephalus may be produced by the Arnold-Chiari malformation in several ways: First, the fourth ventricle or the foramina of Luschka and Magendie may be mechanically obstructed by the squeezing of the medulla and cerebellar tails into the narrow cervical spinal canal. Obstructive hydrocephalus results. Secondly, with less severe traction and constriction the relatively unsupported subarachnoid space may be obliterated at the level of the foramen magnum by pressure of the herniated hindbrain, whereas the fourth ventricle remains patent. The foramina of Magendie and Luschka come to lie below the level of the foramen magnum, allowing free passage of fluid to the spinal subarachnoid space, but no egress from the latter to that of the posterior fossa is possible because of the block at the fora-

men magnum. Communicating hydrocephalus results. Thirdly, owing to the traction on the brain stem there may be mechanical irritation of the arachnoid of the basal cisterns with the production of an aseptic inflammation and plastic exudate that

distinctly smaller than usual, and more numerous. "Wormy" is the most descriptive term for these small convolutions.

The exact nature of microgyria of the diffuse cortical type is not well understood, nor is its

FIGURE 2. *Anterior View of the Spinal Cord at Autopsy in a Case of Arnold-Chiari Malformation.*

Note the upward course of the cervical nerves and the lumbar diplomyelia. The myelomeningocele was located in the lumbar region.

block passage of fluid from the spinal to the cerebral subarachnoid space.

Microgyria and Craniolacunia

Two findings that have not been described previously in the literature as occurring with the Arnold-Chiari malformation are microgyria and craniolacunia. In all 20 cases examined there was conspicuous microgyria. The cerebral gyri were

relation, if any, to the Arnold-Chiari malformation clear. The fact that it was present in each case examined, however, seems worthy of comment.

Craniolacunia, or, as it has been called, caput fenestratum, lacunar skull or *Lückenschädel*, was present in 15 of the cases examined. Its absence in the other 5 cases is subject to question, as it is easily missed at routine post-mortem examina-

tion; this is particularly true if the observer is not familiar with the condition.

Craniofacunia is characterized by a diffuse involvement of the whole skull with rounded defects of varying size in one or both tables, separated by bony ridges. The defects may be wholly devoid of bone. A study of craniofacunia from the roentgenologic point of view has been recently made by Vogt and Wyatt.¹³ These authors found craniofacunia present in 52 (43 per cent) of 120 patients with meningocele and discovered that it was more frequently found with myelomeningocele than with simple meningocele.

The etiology of craniofacunia remains obscure. Theories concerning its relation to increased intracranial pressure are unproved. Vogt and Wyatt considered it to be an unfavorable prognostic sign in meningocele cases. Whatever its significance may be, its high incidence in Arnold-Chiari malformation seems deserving of notice.

Other Findings

Hydromyelia was present in 8 cases. In each of these the coexisting hydrocephalus was of the communicating type. This relation seems significant as regards the genesis of the dilated central canal.

Bony defects of mild degree in the basiocciput were present in 4 cases, and one of these had, in addition, spina bifida of the atlas. Three cases showed a definite degree of platybasia. In another case there was fusion of the cervical vertebrae suggestive of the Klippel-Feil deformity. These bony anomalies of the base of the skull and cervical vertebrae are apparently not of uncommon occurrence with the Arnold-Chiari malformation, but no developmental relation between the two types of defect has been established.

Three of the cases had diplomyelia, or reduplication of the spinal cord. In all cases the lower thoracic and lumbar regions were involved. Herren and Edwards¹⁴ have recently made an exhaustive study of this anomaly, which they believe represents a certain degree of twinning (Fig. 2).

DISCUSSION

From the study of these 20 cases of the Arnold-Chiari malformation and those reported in the literature there is a striking relation between the hindbrain malformation and low dorsal and lumbar myelomeningoceles. These findings suggest that a high proportion of infants with myelomeningoceles seen clinically may be expected to have a coexisting Arnold-Chiari malformation. An analysis was made of 297 cases of myelomeningocele studied at the Children's Hospital between 1929 and 1942. Of these, 5 came to surgical ex-

ploration of the posterior fossa, and 3 of these were later autopsied. In addition, 15 other cases that did not have cerebellar exploration were examined post mortem. In all 20 cases the Arnold-Chiari malformation was present.

The association of the hind-brain malformation with myelomeningocele, as opposed to simple meningocele, seems to be particularly significant in the light of the traction theory of genesis of this anomaly. A large myelomeningocele is likelier to produce fixation of the cord at the site of the spina bifida than is a simple meningocele, or a meningocele sac containing only a few strands of neural tissue. Hence, if the traction theory is valid, the Arnold-Chiari malformation would be expected to occur far more often with large myelomeningoceles than with simple meningeal herniations.

The cases reported in the literature, as well as those under discussion, offer substantiation of this concept.

Although in all the cases reported the protrusion was low dorsal, lumbar or lumbosacral, it is probable that the same mechanism produces a similar but less marked degree of the same anomalous development in upper dorsal and cervical protrusions. Until this condition is produced experimentally, it is not safe to conclude that the traction theory gives the complete explanation of this phenomenon. The microgyria, craniofacunia and other associated anomalies suggest that there is a basic widespread defect. From the information at hand one must conclude that the combination of myelomeningocele, craniofacunia, microgyria and Arnold-Chiari malformation constitutes a clinical entity. It is possible that the easily demonstrable radiographic changes of craniofacunia will provide a simple clue to the diagnosis.

The preoperative recognition of the syndrome is of great importance in planning a surgical attack on the problem. The long-time results of surgical treatment have not been encouraging, but in properly selected cases surgery is definitely indicated. One should not be misled by a short follow-up in these patients, who may do extremely well for a few months or even years and then suffer from recurrent block in circulation of the cerebrospinal fluid. The history of Penfield's⁶ adult patient provides striking proof that the presence of the Arnold-Chiari malformation does not necessarily interfere with full use of the extremities and mental competence. This patient's circulation of cerebrospinal fluid was presumably in a marginal but satisfactory state of balance for many years and might have remained so except for a slight shift in pressure, which promptly created a vicious circle.

Obviously, surgical treatment should be limited to the patients without extensive paralysis of the lower extremities and sphincters. It should not be offered if hydrocephalus is so advanced that it is inconsistent with normal mental development.

dinarily follows in ten days to two weeks. If increased intracranial pressure is a problem in this interval, it can easily be controlled by continuous ventricular drainage. In favor of reversing the order of the two procedures is the fact that the

FIGURE 3. The Arnold-Chiari Malformation as Exposed during Exploration of the Posterior Fossa.

The exact management of the surgical problem must depend on the particular features of the individual case. In general it has seemed to us more satisfactory to excise the meningocele as the first step, freeing the tissues as thoroughly as can be done without damage to functioning nerve tissue. This usually means only a slight increase in mobility of the spinal cord. The findings at this operation occasionally deter one from carrying out exploration of the posterior fossa, which or-

pressure may remain normal following the cerebellar exploration, thus simplifying the management of the meningocele.

In the exploration of the posterior fossa, which can be carried out by a simple midline incision, the essential feature is a wide decompression, including removal of the occipital bone down through the foramen magnum and laminectomy of the upper cervical vertebrae, continuing down until the cord is exposed and the cerebellar tails are

freed (Fig. 3). This is not a particularly formidable procedure if carried out with due respect for the anomalous venous channels usually present in the dura.

It is hoped that in the future we may be able to select more certainly those patients who should be subjected to this operative procedure. Although it is possible to demonstrate the malformation by air injection, it has not been satisfactory to date to use this method to distinguish the promising from the hopeless cases. Electroencephalography holds definite promise of identifying the associated microgyria, which is probably a contraindication to operation.

SUMMARY

Twenty cases of the Arnold-Chiari malformation associated with myelomeningocele have been studied, and the literature has been briefly reviewed.

The anomalous development has been strikingly similar in all cases.

The majority of the patients had associated microgyria and cranioleucania.

The outlook is poor in most cases, but prom-

ising cases should be carefully selected and subjected to surgical treatment.

MEDICAL PROGRESS

THE MODIFICATION OF INTESTINAL MOTILITY BY DRUGS*

FRANZ J. INGELFINGER, M.D.†

BOSTON

ALTHOUGH the effect of drugs on intestinal motility is an ancient and well-worn subject of investigation, it is only within relatively recent times that observations have been carried out on untraumatized intestinal loops of normal animals and of man. In such experiments, the artefacts and abnormal responses that attend anesthesia, decapitation, shock and local trauma of the bowels are eliminated, and a truer picture of motility, both in the normal state and as influenced by drugs, is obtained. Procedures using intact intestinal loops are not designed to differentiate the function of longitudinal and circular muscles or to answer similar questions of basic physiologic interest. In evaluating the total effect of a drug on human intestinal motility, however, results of investigations using the intact bowel, particularly

the bowel of man, are of paramount significance. For this reason, emphasis will be placed, whenever possible, on the results obtained from human experimentation.

Even if intact bowel loops in one species are used, considerable variation in the intestinal reaction to drugs can be observed, depending on such factors as the dose and route of administration of the drug, the activity and the content of the intestine at the time of the experiment and the technic used in recording motility. In interpreting the results of any pharmacologic study of intestinal motility, it is therefore necessary to take these factors into account. In particular, the advantages, disadvantages and properties of different technics must be understood before apparently contradictory observations can be correlated.

Five general methods are used in recording the motor activity of the bowels in situ. These are direct observation, roentgenologic and fluoroscopic studies, kymographic recording by balloons, re-

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C. Thomas Company, 1942. \$5.00).

cording by devices attached to smooth-muscle groups, and recording of intraenteric pressures.

“Direct observation (O).”* The intestinal movements may be observed with the naked eye or by photographic means. Usually the intestinal loops are surgically exposed, but occasionally the intestinal activity within a thin-walled hernial sac may be studied. The method eliminates nonphysiologic stimuli within the bowel, but external stimuli resulting from surgical exposure are not excluded. The greatest disadvantage of this technic arises from the fact that the complexity of intestinal movements makes accurate interpretation extremely difficult.

“Roentgenologic and fluoroscopic studies (X)” With this method, the normal physiology of the intestinal tract is least disturbed, although the question may be raised whether the bowel handles the barium suspension in a manner similar to its handling of foodstuffs. On the other hand, this method merely shows the end result of several interacting forces that may or may not give an indication of the motility of the organ under investigation. For example, the rate of gastric emptying, which is often used as a criterion of the stomach's motor activity, may be delayed by high intraduodenal pressures as well as by gastric atony.

“Kymographic recording by balloons (B).” Balloons can be inserted within a hollow viscus and its contractions recorded kymographically by various means. A balloon method free of objectionable features has yet to be devised, since the presence of the balloon in the intestines serves as a constant and abnormal source of stimulation. Furthermore, balloons occasion more or less intestinal obstruction, are nondispersible boluses in organs that for the most part transport dispersible liquids, and are subject to a variety of influences besides those of local muscular contraction. Nevertheless, the fact that the balloon method lends itself to graphic recording is a tremendous advantage, and if used with due consideration of its limitation, this method yields important results. Balloons can be inserted in intestinal loops that have been opened by surgical means, or they can be used in the intact bowel of man by the Miller-Abbott technic of intestinal intubation.

“Recording by devices attached to smooth-muscle groups (M).” In surgically exposed loops of bowel, recording devices can be attached to muscle groups of varying size and extent. This technic is precise and allows the action of longitudinal and circular muscles to be differentiated.

*This and the other four symbols denote the method employed in the experiments cited.

On the other hand, it requires surgical procedures and by itself gives no indication of the forces within the bowel.

“Recording of intraenteric pressures (P).” This method has been attempted by only a few investigators^{1,2} and no complete pharmacologic studies have yet been carried out by this method. Before the full picture of a drug's effect on intestinal motility can be drawn, however, its effect on intraluminal pressures as well as on muscular activity and transport of contents must be studied.

Not only method but phraseology has suffered from lack of standardization. In order to avoid confusion, the following definitions of terms used in this review are given:

Transport. The advance of intestinal contents, whether chyme, barium, balloons or other material, is referred to as transport.

Tone. The tone of the intestine is considered to be the caliber that it maintains in the face of a distending force. This force may vary considerably depending on the method of investigation.

Waves. A tremendous number of terms have been used to describe the wave patterns created by intestinal motility. The most desirable terminology is one that labels waves with letters or numerals and avoids the implication that wave patterns and their effect on transport are identical. Unfortunately, this terminology is limited to methods employing graphic recording. In this review, which includes material obtained by nongraphic methods, wave patterns will be divided into “propulsive” and “mixing” types. Under the heading of propulsive waves fall such terms as “peristaltic waves,” “mass peristalsis,” “Type II waves” of the colon³ and “L waves” of the small intestines,⁴ whereas mixing waves include “rhythmic segmentation,” “Type I waves” of the colon and “S waves” of the small intestine. The adjectives “propulsive” and “mixing,” as used here, describe wave patterns and do not necessarily indicate propulsion or mixing of intestinal contents. Thus, under certain conditions, no transport may occur even when propulsive waves are in evidence, and vice versa, chyme may flow downstream when only mixing waves are present.

Motility. This term, often used incorrectly as synonymous with “transport,” refers to the total spontaneous muscular activity of the intestine. The three component parts of motility—tone, propulsive waves and mixing waves—interact to exert a certain force on the intestinal

contents. Actual transport, however, depends not only on the forces created in any one intestinal area but also on the motility and intraluminal pressures of adjoining areas. As a general rule, a low tone and frequent propulsive waves of large amplitude are conducive to transport, whereas a high tone, which eliminates effective "diastole" between waves,⁵ or a low tone with absent propulsive waves, or inco-ordination of adjoining intestinal segments,³ retards transport. In many reports, motility is called propulsive or nonpropulsive depending on its effect on transport.

GENERAL EFFECTS OF DRUGS

When the intestine is subjected to a pharmacologic action, tone, propulsive waves and mixing waves may be uniformly affected, or the drug may act predominantly on any one of these factors. If this important concept is kept in mind, many apparent contradictory pharmacologic effects will be explained. Thus, a drug may stimulate motility by inducing a marked spasm—that is, high tone—but for reasons given above, it will decrease transport. Vice versa, a drug may decrease motility by reducing both tone and wave activity, but if the major effect of the drug is on tone, transport of intestinal contents may be increased. Quite apart from their specific effect on intestinal motility, drugs may influence transport in other ways. If transport is inhibited because an unco-ordinated motility obtains in two adjoining intestinal areas, exhibition of a drug may co-ordinate motility and facilitate transport regardless of the specific action of the drug. Another possible factor, about which little is known, is the effect of drugs on the quality and quantity of intestinal secretions and on the speed of absorption. If these are changed, intrainestinal pressures vary accordingly, even if motility is constant, and the rate of transport may be altered. Considerations such as these show why it is most difficult to determine the actions of a drug merely by observing its effect on intestinal transport.

Drugs may influence intestinal motility through a variety of routes. Some affect the irritability of the musculature directly. Others mimic, enhance or inhibit the action of the humeral agents that are believed to transmit impulses from the nervous end organs to the effector cells. As a rule, drugs that favor the transmission of cholinergic (parasympathetic) impulses stimulate motility, whereas drugs that favor the transmission of adrenergic (sympathetic) impulses depress motility. The supposedly reversed effect of these agents on the intestinal sphincters plays a very minor role in controlling transport of intestinal contents. Quigley

and his associates⁶ have shown, for instance, that gastroduodenal pressure gradients, which reflect gastroduodenal motility, are of more importance in controlling gastric emptying than is an independent action of the pyloric sphincter (P).

DRUGS RETARDING TRANSPORT

Morphine

The confusion and contradiction concerning the action of morphine and its related alkaloids on intestinal motility have gradually been cleared away during the past decade. Much of the credit for this achievement belongs to Quigley, Highstone and Ivy,⁷ who urged that propulsive be distinguished from nonpropulsive motility, and to Abbott and Pendergrass,⁸ who demonstrated the feasibility of using the intact small bowel of normal man for pharmacologic studies.

When clinical doses of morphine are injected subcutaneously, a marked rise in tone involves the whole intestinal tract within a few minutes. In the human duodenum, the increase in tone is of sufficient intensity to obliterate the lumen (B and X).⁵ Concomitant with this tonal spasm, the amplitude of the mixing waves is decreased but their frequency is increased; whereas propulsive waves are completely abolished, partly because of the high tone that prevents diastolic relaxation. Similar but less prompt and striking changes occur in the jejunum and ileum. Except for an initial spurt caused by the rising tone, transport is almost completely abolished. The characteristic duodenal spasm that follows the administration of morphine may, in fact, reverse the direction of transport and may play a part in the nausea that at times attends this drug's exhibition (B and X).⁸

After a period of about thirty minutes, the tone of the small intestine drops to a low level and remains depressed for four hours or even longer.⁵ Propulsive waves continue to be absent. As a result, transport, which is initially delayed by spasm, is subsequently delayed by atony.

The response to morphine of the human ileum at or near an ileostomy is also characterized by an increase in tone, increased frequency of mixing waves (M)⁹ and a decrease in propulsive motility (B).¹⁰ In these cases the effect of morphine is more pronounced, and the increase in tone of longer duration (two to three hours), than is found to be the case in the normal intact ileum.⁵ An ileostomy may, however, considerably alter ilcal function, as may the disease for which the ileostomy is performed. Hence, the observations made on the intact viscus are probably more indicative of the small bowel's response to morphine.

The careful studies (B) of Adler, Atkinson and Ivy^{10, 11} show that the colon of both man and the

dog react to morphine in roughly the same fashion as does the small bowel. Nonpropulsive motility—that is, the tone and the amplitude of mixing waves—is increased, but propulsive motility is strikingly diminished. In the colon, however, the elevated tone persists for two to three hours. Whether a late fall in tone ever occurs has not been reported.

Animal experimentation in recent years has yielded consistent results in that morphine is generally found to have a stimulating effect on intestinal motility, but in other respects the observations are more variable. It is, for instance, recorded that morphine abolishes peristaltic waves (B),¹² increases the amplitude of peristaltic contractions (B),¹³ and produces intermittently recurring tonus waves (O).¹⁴

Human experimentation is not invariably attended by consistent results,¹⁰ and at times some areas in the colon may be relaxed while the greater part of this organ is exhibiting a high degree of nonpropulsive motor activity (B).¹⁷ Nevertheless, the evidence is unequivocal that in man morphine usually increases tone and decreases propulsive motility. In the small intestine, a period of atony succeeds the period of hypertoncity. Whether spasm, atony or lack of segmental co-ordination obtains, however, the result is the same: transport of intestinal gas and chyme is seriously retarded.

The clinical application of these facts is clear. Unless morphine is needed for its unsurpassed analgesic action, it should not be used in treating nausea and vomiting, conditions in which intestinal transport is already seriously deranged. Nor, contrary to some opinion, is morphine to be used for the express purpose of treating or preventing paralytic ileus. In patients with partial mechanical obstruction, morphine may relieve pain by abolishing the marked fluctuations in intraenteric pressures produced by huge propulsive waves, and the initial increase in tone may elevate the basal intraenteric pressure (P),² but expulsion of the trapped contents will not be furthered. In this connection, it may be added that the duodenal spasm that attends the use of morphine often makes therapeutic intubation of the small intestine very difficult. If possible, therefore, intubation should be attempted before heavy doses of morphine are given.

Heroin, Dilaudid, Pantopon, apomorphine and codeine have the same qualitative effect on intestinal motility as does morphine (X).¹⁶ (B) ^{13 17 18} The action of codeine and apomorphine is relatively weak, whereas 1 to 2 mg of Dilaudid produces the same results as does 8 to 10 mg of morphine (B).¹⁰

Papaverine, unlike the other opium alkaloids, is known to inhibit motility. In man, its intravenous injection usually reduces the tone of the colon (B),¹⁸ but most studies on the intestinal effects of this drug have been confined to excised intestinal strips.*

Adrenalin

Intestinal motility should theoretically be inhibited by adrenalin or other sympathomimetic drugs and by drugs that antagonize the action of cholinergic nerves. The use of adrenalin for this purpose is unfortunately of little avail. In the first place, the results obtained with adrenalin are often variable and unpredictable. Not infrequently it has been reported to exert a stimulating effect on motility, most recently by Wells et al.,¹⁹ who noted that intra arterial injections of adrenalin increased the circular contractions in the distal colon of animals (B and M). In other loops of the dog's colon (B),²⁰ and in the small intestines of dogs (B)²¹ and man (O),²² the reaction is more what one would expect, in that a constant intravenous injection of adrenalin causes a decrease in tone and an inhibition of wave activity. After a period of two to three minutes, however, intestinal motility breaks through this inhibiting effect, even though the injection rate of the adrenalin is accelerated.

Although subcutaneous injections of adrenalin have at times induced relaxation in the human bowel (B),²³ no clear cut or consistent effects are usually observed. This is true of the intact human small intestine (B)²⁴ as well as other preparations. The usual explanation advanced for the inability of adrenalin to effect intestinal motility is that clinical doses that might be effective elicit marked cardiovascular responses.²⁵ Youmans,^{26 27} however, has shown that the dog's intestine (B), particularly if sensitized by denervation,²⁸ responds to intravenous adrenalin in amounts that are less than the minimal pressor dose. Hence, the variable response of intestinal motility to subcutaneous administration of adrenalin may be partly due to the bowel's tendency to escape from the influence of a constant supply of this drug.

Amphetamine

The search for a sympathomimetic amine that specifically inhibits intestinal motility has not yet borne fruit. Some hope was held for amphetamine (Benzedrine) because it appeared to relax spasm and enlarge the lumen of the small and the

*Batterman²⁹ in studying the actions of the synthetic substance 1-methyl-4-phenyl-piperidine-4-carboxylic acid ethyl ester hydrochloride (Demerol) found that human intestinal motility is depressed by this drug. A review of the literature by Batterman and Himmelfach³⁰ reveals, however, that this spasmolytic effect is not always obtainable.

large bowel (X).²⁹ This observation was partially confirmed (X)³⁰ and also contradicted (X).³¹ Balloon records of the human small intestine show that if any response attends the exhibition of amphetamine sulfate (15 to 20 mg.), this response tends to consist of a moderate reduction of tone and wave activity (B).³² In half the cases, however, motility is unaltered. The reactions of the human colon are no less equivocal; only occasionally is tone depressed and the amplitude of propulsive waves lessened (B).^{15, 32, 33} Local application of a 0.5 per cent solution of amphetamine sulfate to the human rectal mucosa, examined by means of a proctoscope, is also without motor effect.³⁵

Atropine

Atropine, when used in clinical doses, depresses all phases of intestinal motility. On this point, almost all recent studies concur, whether carried out in dogs (B)^{11, 36, 37} or in man (M),⁹ (O),²² (B)³³ and (B and X).³⁸ Although the efficacy of atropine in inhibiting intestinal motility varies with the dose, 0.6 mg., given subcutaneously, is usually sufficient to lower tone, abolish propulsive waves and decrease the amplitude of mixing waves in the small bowel of man (B and X).³⁵ In the human colon, similar results are obtained with 0.75 mg. (B).^{15, 33} Interestingly enough, the effects of atropine are more marked in the distal than in the proximal colon of the dog (B).¹¹ From the fact that the uniformly depressed tone is unrelieved by propulsive waves, it can be deduced that transport is markedly retarded by atropine.

Following subcutaneous injection, the effects of atropine take place in fifteen to thirty minutes and persist for one to two hours. Intravenous administration of the drug elicits more marked effects of more rapid onset; oral administration produces less pronounced changes in thirty to forty-five minutes.

The question may legitimately be raised why atropine, which is such an effective antispasmodic in experimental studies, is often a source of disappointment in clinical use. Two observations may offer a partial answer. It has been known for some time that atropine effectively abolishes a response to injected acetylcholine, but that it is much less effective in counteracting vagal stimulation. Recently this phenomenon has been quantitated in animals with regard to the pelvic nerve (B and M).¹⁹ Whereas atropine inhibited 97.5 per cent of the stimulating effect on colonic motility of intra-arterially injected acetylcholine, it inhibited only 88.6 per cent of the effect produced by stimulating the pelvic nerve electrically. The usual explanation advanced to account for

this discrepancy is that atropine can act to inhibit acetylcholine on cell surfaces, but cannot act on acetylcholine released by nerve fibers, which may end within the cell.³⁴ The problem has, however, been examined further by Youmans and his collaborators³⁵ who have presented evidence that atropine inhibits intestinal motility in amounts less than that needed to inhibit the intestinal vagus (B). On the basis of this and related evidence, they suggest that the motor activity of the intestines is maintained at a basal level by acetylcholine produced by the myenteric plexuses, and that this basal function operates in the absence of stimulation by extrinsic nerves. The administration of atropine, according to this concept, makes the intestinal musculature unresponsive to acetylcholine produced at basal levels but has less effect on the humoral agents released by the extrinsic nerves. If this is the case, one can understand why atropine shows to such good advantage in experimental studies attempted at basal levels, whereas in functional or organic abnormalities of the intestine, in which the extrinsic nerves may play an important role, the results of atropinization are less favorable. On the other hand, the hypermotility of the rectosigmoid that at times follows prevertebral ganglionectomy in dogs is inhibited by intravenous atropine (B).³⁹

The efficacy of an antispasmodic can be tested under other than basal conditions by observing its action on the intestine rendered spastic by a previous or simultaneous injection of morphine.¹⁵ That the hypermotility produced by morphine is in any way analogous to the hypermotility seen in intestinal disorders has not been proved, although one school of thought holds that the action of morphine on the bowel is essentially cholinergic.⁴⁰

To a certain extent, the action of morphine and that of atropine on intestinal motility are antagonistic. In the dog, small doses (1 mg.) of atropine decrease the transient propulsive motility that occurs after a sizable dose (16 mg.) of morphine is given, but the increase in tone and in mixing waves is not affected. Both the propulsive and nonpropulsive motility stimulated by smaller doses of morphine are, however, antagonized by 1 mg. of atropine (B).^{11, 12} If these results are applied to man, it is seen that toxic doses of atropine would have to be used to abolish the spasmotic effect of clinical doses of morphine. Actual experiment bears out this assumption: 0.7 mg. of atropine sulfate only partially inhibits the spasm produced by 8 mg. of morphine (B).¹⁵ Since both atropine and morphine inhibit transport, it is understandable that this effect should be pronounced when both drugs are exhibited together.

Atropine Substitutes

A number of compounds have been synthesized that appear to inhibit intestinal motility without provoking the side reactions characteristic of atropine. Three of these compounds are in quite extensive clinical use: novatropine, Syntropan, and Trasentin. Methyلاتropine nitrate (Eumydrin) has also been used, especially in the treatment of hypertrophic pyloric stenosis; but although its effectiveness equals that of atropine, its toxicity, at least in mice, is three times as great (M).⁴¹

Pharmacologically and in its effect on the dogs' intestinal motility, novatropine closely resembles atropine (B).³⁷ Trasentin produces a moderate reduction of the colonic tone in man and decreases the frequency and irregularity of propulsive waves (B).²⁵ It appears to be more effective in this respect than is Syntropan (B).^{15, 33} The problem deserves further study, however, especially since in most investigations Trasentin has been used in an injectable form, a preparation that the manufacturers have discontinued because of its instability.

Syntropan and Trasentin, unlike novatropine, are said to exert a direct muscle-depressing action as well as an atropine-like inhibition of cholinergic impulses (B).^{42, 43} In view of this fact, one might suppose that these compounds could inhibit the motor effects of morphine more successfully than does atropine. Although this expectation was realized for Syntropan in the case of the dog (B),⁴⁴ Trasentin was found to be not quite so effective as atropine in reducing morphine-induced hypertonus (B).¹⁵ There is also evidence that morphine and Trasentin should not be used concurrently,¹⁶ although this combination exerts no noxious effects on respiration in the dog.⁴⁵

DRUGS ACCELERATING TRANSPORT

Prostigmine

Intestinal motility is theoretically stimulated by acetylcholine or its esters, by drugs that inhibit the activity of cholinesterase and by those that antagonize the action of the adrenergic nerves. The most satisfactory drug for this purpose is undoubtedly Prostigmine, which, like physostigmine, inhibits cholinesterase. Unlike physostigmine, however, Prostigmine is practically devoid of any unpleasant side reactions.

When 0.5 mg. of Prostigmine is given subcutaneously the intact human small intestine responds with a moderate increase in tone and in the frequency and amplitude of the propulsive waves (B).²⁴ In patients with stomas of the large and the small bowel, a similar stimulation of motility is observed (B).^{46, 47} In dogs, the effect is more

pronounced in the colon than in the jejunum (B).⁴⁶ Since propulsive motility is augmented (B),⁴⁷ transport is promoted. One may conclude that in the small and especially in the large bowel, Prostigmine prevents areas of atony, stimulates propulsive waves and co-ordinates these two components of intestinal motility to facilitate transport and expulsion of intestinal contents. Little wonder, then, that Prostigmine is the drug of choice in combating ileus or other conditions where a functional derangement of intestinal transport exists.

Prostigmine Methylsulfate, like atropine, is rather slow in taking effect. A definite change in intestinal motility may not take place until ten to thirty minutes after its intramuscular injection. When Prostigmine Bromide is given orally, its effect may not be noticeable for two to four hours.⁴⁷

Schwartz and his co-workers⁴⁶ believe that Prostigmine must exert a direct stimulating effect on intestinal smooth muscle as well as inhibit cholinesterase, because this drug is effective in certain diseases of the digestive tract in which inflammation or anoxia of the intestinal tissues conceivably might impair the humoral transmission of nerve impulses. In support of this belief, they have shown in dogs that repeated intravenous injections of Prostigmine bring about a slight increase in motility even when the animal is atropinized. It is not generally held, however, that Prostigmine has any direct action on the enteric musculature.⁴⁸ In well-established cases of sprue, for example, in which the myenteric nervous system is thought to be damaged, Prostigmine in 0.5-mg. doses may produce no change in the motility of the atonic small bowel (B).⁴⁹

Ergotamine

Ergotamine is generally supposed to block adrenergic excitatory effects specifically.⁵⁰ Darrow,⁵¹ on the other hand, holds that ergotamine primarily blocks the adrenergic inhibitory effects by "a protection of parasympathetic activity or a physostigmine-like action." This theory is particularly germane to the important work done by Adler, Atkinson and Ivy⁴⁷ on the supplementary action of drugs that stimulate intestinal motility (B). These authors found that small doses of ergotamine have no effect on motility of the human colon, but that ergotamine and Prostigmine potentiate each other markedly. If 0.25 mg. of ergotamine is injected with 0.25 mg. of Prostigmine, the stimulating effect on propulsive motility exceeds that following the administration of 0.5 mg. of Prostigmine, and colonic transport is very active. Oral administration of 1 mg. of ergota-

CASE 29281

PRESENTATION OF CASE

A sixty-four-year-old fisherman entered the hospital because of an "aching pain in the small of the back."

Five weeks before entry while pulling a dory onto the beach, he experienced rather sudden pain in the small of the back and under the left shoulder blade. A physician strapped his back, but this afforded little relief. The pain intermittently recurred, and about three weeks later the backache became gradually more severe and at times on exertion a sharp pain radiated from the back around to the left anterior costal margin. During the week prior to admission the pain became constant and seemed to be in the region of the eighth and ninth dorsal vertebrae. During that time he lost his appetite and felt weak but had no specific gastrointestinal complaints, such as nausea, vomiting, gas, abdominal pain and jaundice. The patient had always been constipated but in the two weeks prior to admission he believed that the constipation was severer. At no time did he recognize bloody or tarry stools. During the previous two months he had lost 15 to 20 pounds.

The family history was noncontributory. For many years the patient had had a chronic cough occasionally productive of small amounts of brownish sputum. At no time was the sputum blood streaked, and repeated sputum examinations were said to have been negative for tubercle bacilli, though "roentgenographic studies showed some trouble in the lungs." Thirty years before entry he had had "bronchitis" and occasional night sweats.

Physical examination disclosed a thin, apprehensive man who complained bitterly of acute, constant, low-back pain. The examination of the heart was normal. There was a 3-cm. firm, exquisitely tender mass at the angle of the left tenth rib. There was dullness with increased voice sounds and bronchovesicular breath sounds at the right apex anteriorly and at both lung bases; fine

moist rales were audible at both lung bases posteriorly. The abdomen was difficult to examine because it was held tense, apparently as a result of the patient's fear of further discomfort. No masses were felt and no tenderness could be elicited. The abdomen was tympanitic, and normal peristalsis was present. There was slight limitation to forward bending of the neck, without pain or a positive Kernig's sign. There was exquisite tenderness over the spinous processes of the tenth to twelfth dorsal vertebrae, with some tenderness of the posterior portions of the tenth, eleventh and twelfth ribs; however, no muscle spasm could be detected. The extended legs were easily flexed on the trunk without pain. The arms and legs were normal except for varicose veins of the legs, more marked on the right. Several examiners felt a superficial, movable lymph node in the left supraclavicular region. The prostate was small and rather hard, but was not tender. No rectal masses were felt. A neurologic examination demonstrated reflexes within normal limits. Vibration sense was diminished at the ankles, more so on the left. Sensation was normal except for hyperesthesia, particularly on pressure upon the twelfth dorsal spinous process and the right tenth rib in the midclavicular line. There was marked longitudinal ridging of the nails.

The blood pressure was 124 systolic, 88 diastolic. The temperature was 98°F., the pulse 80, and the respirations 20.

Examination of the blood revealed a red-cell count of 3,830,000, with a hemoglobin of 70 per cent, and a white-cell count of 18,420, with 86 per cent neutrophils, 10 per cent lymphocytes and 4 per cent monocytes. Twenty-four hours later the white-cell count was 20,400. The urine was normal. A blood Hinton test was negative. A tuberculin (1:50,000 dilution) test was negative. Examination of the sputum and gastric contents was negative for acid-fast organisms. The clotting time was 4 minutes; the bleeding time, 19 minutes. The stools were guaiac positive on two occasions and negative on three subsequent examinations. The nonprotein nitrogen was 28 mg. per 100 cc., the chloride 102.1 milliequiv. per liter, the van den Bergh 0.85 mg. direct and 1.2 mg. indirect, the protein 4.9 gm. per 100 cc., the albumin being 2.3 gm. and the globulin 2.6 gm.—an albumin globulin ratio of 0.88. The calcium was 10.0 mg., the phosphorus 4.6 mg. and the phosphatase 17.6 Bodansky units per 100 cc. A lumbar puncture revealed an initial pressure of 75 mm. of water; the dynamics were normal. The spinal-fluid protein was 51 mg. per 100 cc.; the fluid did not contain cells. The gold-sol curve was normal.

*On leave of absence.

An x-ray film of the lower dorsal spine demonstrated marked degenerative changes—spurring and lipping—consistent with hypertrophic arthritis; there was no definite evidence of metastases. The rectum and cecum filled without delay during a barium enema. No evidence of disease of the rectum and large bowel could be demonstrated. A chest roentgenogram revealed that the diaphragm was low in position, and fluoroscopy showed impaired respiratory motion. The lung fields were large and bright and were not involved by disease. The precordial space was large. Both upper lung fields contained string-like areas of increased density with some flecky areas, particularly on the left side. The left hilus was elevated. There was a circumscribed area of consolidation in the anterolateral portion of the left lower lobe close to the diaphragm. The pleura showed evidence of thickening in this region. Far posteriorly on the left side, superimposed on the shadows of the fifth and sixth dorsal vertebrae, was a soft-tissue mass with a sharply defined convex anterior border that blended smoothly with the pleura. It was not visible in the anteroposterior view. The seventh and eighth dorsal vertebrae were slightly wedged, but they showed no evidence of bone destruction. Following a barium meal, examination of the upper gastrointestinal tract showed a normal esophagus. The stomach appeared large, atonic and moderately dilated and contained a large amount of fluid. Barium passed readily through the somewhat widened first, second and third portions of the duodenum with a to-and-fro motion in the second and third portions. Fluoroscopically the duodenum was slightly narrowed near the ligament of Treitz and barium passed through the area in splashes; no actual obstruction was present, and no evidence of intrinsic or extrinsic disease could be demonstrated on the films.

On the eighth day after admission the patient seemed more comfortable, although he had only been treated symptomatically. The swelling over the tenth rib had decreased in size. On the following day, however, he was markedly dyspneic. The back pain, however, had disappeared. The temperature was 101°F. The sclerae were slightly icteric, and the skin had a slight lemon tint. Dyspnea was severe, but the lungs were clear except for crackling rales at the left base. The heart could not be satisfactorily outlined because of moderate emphysema. The neck veins were distended and pulsating but the wrist pulse was regular. The blood pressure was 120 systolic, 50 diastolic. The abdomen was tense and tympanitic. Examination of the blood revealed a red-cell count of 1,040,000, with a hemoglobin of 6.3 gm., and a

white-cell count of 35,000, with 54 neutrophils, 5 per cent metamyelocytes, 9 per cent myelocytes, 16 per cent questionable blast forms, 13 per cent lymphocytes, 2 per cent monocytes and 1 per cent basophils. The platelets were markedly depressed, and there was marked anisocytosis, poikilocytosis and polychromatophilia of the red cells. The blood picture remained essentially the same for the next few days. He gradually became extremely disoriented and died twelve days after admission.

DIFFERENTIAL DIAGNOSIS

DR. RULON W. RAWSON: To summarize, we have a sixty-four-year-old fisherman complaining of an increasingly severe backache, anorexia, weakness and loss of weight. The significant physical findings were tenderness over the lower dorsal spinous processes and over the posterior portion of the lower ribs, a palpable supraclavicular lymph node and terminal jaundice. The significant laboratory findings included a moderate hypochromic anemia that changed to a marked hyperchromic anemia associated with an impressive myelogenous leukemoid picture, a low blood protein and an elevated blood phosphatase. X-ray examination revealed unusual shadows in the left lung field, nothing definite in the gastrointestinal tract and no evidence of spinal metastasis, although the seventh and eighth dorsal vertebrae were wedged.

The finding of a supraclavicular node, two masses in the chest cavity, pain in the back, a myelophthisic anemia and an increased blood phosphatase suggest a widespread neoplastic process with metastases to the lymph nodes, spine, ribs and bone marrow and a primary or secondary carcinoma in the chest. The low total protein points to liver disease, as does the late finding of jaundice. The increased blood phosphatase might have been due to liver metastases, as well as to an osteoblastic reaction around a metastatic lesion in the skeleton. The dilated stomach and duodenum, with the described to-and-fro movements in the distal part of the duodenum, indicate some obstruction distal to the lower third of the duodenum. Primary tumors of the small bowel are so rare that I shall not consider such a diagnosis and shall explain the apparent obstruction on the basis of pressure from retroperitoneal lymph nodes containing metastatic cancer.

The slightly increased spinal-fluid protein with the rather low initial pressure might indicate a partial block due to spread of disease from the involved vertebrae to the spinal canal.

The most obvious diagnosis to make is that of bronchiogenic carcinoma with generalized metastases. Carcinoma of the prostate with metastasis

might give a picture similar to the one presented by this patient. However, with carcinoma of the prostate it is commoner to see definite x-ray evidence of disease involving the pelvis and spine and less common to see metastases to the liver, lungs and retroperitoneal nodes. Lymphoma might also produce this picture. At this man's age the Hodgkin's or reticulum-cell sarcoma types would be the ones to consider. However, the spleen was not described as palpable and only one peripheral lymph node was felt. It is my impression that jaundice is a rare finding in lymphomatous disease. The blood picture is suggestive of a myelogenous leukemia, but I prefer to interpret it as indicative of a myelophthisic anemia due to bone-marrow metastases. My diagnosis is bronchiogenic carcinoma with metastases to the pleura, vertebrae, ribs and liver and to the mediastinal, retroperitoneal and left supraclavicular lymph nodes.

DR. GEORGE W. HOLMES: I find it a rather complicated job for me to interpret even what is said in the text here. I shall try to point out as many of the things as I can. First, I think we can rule out the gastrointestinal tract as a source of trouble. There is nothing in the text that points to disease, and certainly I am not able to see anything in the films.

So far as the spine is concerned, it is obvious that there are spur-like formations, which are not uncommon in people past middle life. I should not expect that to cause any trouble except vague back pain. I do not believe that the "wedge-shaped vertebrae" are of great clinical significance in an old person with marked curving of the spine. If each were accompanied by a widening of the body and a destructive process in the bone, one would have to pay attention to them. I do not see anything of that kind, however, and I am inclined to put little weight on that part of the findings. The anterior margin of the tenth or eleventh dorsal vertebra shows a concave defect. It is not very clear on this film, which is the only one we have. I shall have to leave the spine without giving any help.

The chest shows an obvious lesion. The hilus was said to be high on the left side, which is obvious. That usually means either fibrosis in the lung or a partial collapse of a lobe—something contracting the upper part of the chest. The films also show a good deal of change in the substance of the lung in the upper part of the chest, probably the upper lobe, and at the base there is obliteration of the costophrenic sinus. On the right side I think the diaphragm is normal. The low position may not mean anything or may mean the patient had a moderate degree of emphysema. According to the fluoroscopic examination there

was no marked limitation of the movements of the diaphragm, which one would expect with emphysema.

CLINICAL DIAGNOSES

Metastatic malignancy, primary site undetermined.

Myelophthisic anemia.

DR. RAWSON'S DIAGNOSES

Bronchiogenic carcinoma, with metastases to vertebrae, ribs, liver, pleura and mediastinal, left supraclavicular and retroperitoneal lymph nodes.

Myelophthisic anemia.

ANATOMICAL DIAGNOSES

Adenocarcinoma of stomach, with metastases to pleura, lung, vertebrae, ribs and mediastinal, left supraclavicular and retroperitoneal lymph nodes.

Myelophthisic anemia.

Hematopoiesis of spleen and liver.

Neoplastic thrombosis of small pulmonary arteries.

Pulmonary tuberculosis, healed.

Pulmonary infarct.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: As Dr. Rawson predicted, this man had a myelophthisic anemia. The vertebral and femoral marrow was almost completely replaced by metastatic carcinoma. In these cases the spleen and, if the marrow replacement is widespread, the liver take on the function of manufacturing red cells, and such was the case here. Both the liver and spleen had foci of hematopoiesis. The primary site of the cancer was not in the lung, but in the cardia of the stomach, 1 cm. below the cardiac orifice on the lesser curvature. I suppose that if the patient could have been stood on his head during the x-ray examination it could have been seen. The two positive guaiac tests on the stools furnished the only lead.

A PHYSICIAN: How do you account for a decrease of over 2,000,000 in the red-cell count during his short hospital stay?

DR. CASTLEMAN: A tremendous loss of red cells in nine days certainly suggests hemorrhage, but there was no evidence of it in the gastrointestinal tract or anywhere else.

A PHYSICIAN: Why did he have a white-cell count of 35,000?

DR. CASTLEMAN: That is unusual, but it may be moderately elevated in myelophthisic anemia.

I am quite sure he had nucleated red cells in the smear, which were not recorded. But nucleated red cells are rarely noted in any hematologic examination so I always assume they are there when I want to have them. One other finding was quite interesting and may have had something to do with the distended pulsating veins in the neck: the patient had no pulmonary emboli, but every small artery in the lung was filled either with tumor thrombus or with secondary fibrous thrombosis, so that he had, in the terminal stages, an acute cor pulmonale. A similar case was described several years ago by Brill and Robertson.* In their case also, the primary carcinoma was in the stomach.

DR. RICHARD CHUTE: Was the back pain due to pathologic fracture?

DR. CASTLEMAN: We did not find any major destructive lesion in the vertebra, although there was diffuse tumor destruction in the marrow. When I read the story through I thought of cancer of the pancreas because I have seen a number of cases of cancer of the tail of the pancreas in which the patients had attended the Orthopedic Clinic anywhere from six months to two years, getting one back brace after another until finally the tumor mass was apparent. This man had a number of enlarged lymph nodes about the celiac axis in immediate apposition with the pancreas but not involving it. I am inclined to think that there was direct nerve invasion at that point, which was the source of the pain. That is a guess however.

DR. HOLMES: Is there any reason why the lung hili were high?

DR. CASTLEMAN: Yes; the patient had old fibrotic processes at both bases, which I think quite certainly were due to healed tuberculosis. He also had an area of fibrosis at the left base that looked like a healed infarct of many years' standing.

DR. HOLMES: We have recognized for some time that widespread cancer in the bone marrow can exist without changes in the bone by x-ray. I perhaps should have mentioned that in discussing the case.

DR. CASTLEMAN: There were no liver metastases. The soft-tissue shadow seen on the x-ray film close to the dorsal vertebrae was a metastasis to the sixth rib, which formed an elliptical soft-tissue mass near the costovertebral junction. Similar but smaller metastases involved the ninth and tenth ribs on the left side.

CASE 29282

PRESENTATION OF CASE

A sixty-five-year-old man, a woolworker, entered the hospital because of jaundice and itching of the skin.

He was well until four months prior to admission when he noticed the onset of itching of the skin. He considered this a "yarn itch" since many other workers had had the same trouble and "scratched the hide off themselves." Three and a half months before entry he experienced on two occasions, a week apart, a sudden, cramping, diffuse, lower abdominal pain, which lasted only a few minutes and was not severe enough to double him up or force him to stop working. There was no nausea, vomiting, fever or chills. At about that time he developed a dislike for fatty foods and noticed that his urine had become much darker in color and his stools clay colored, but there was no change in bowel habits. Two and a half months before entry he developed anorexia and felt so tired that he had to give up work. His physician told him that the itch was not "yarn itch" and gave him a lotion; he went to work in a shipyard. Two months before admission his fellow workers noticed that he was jaundiced. The jaundice gradually deepened, and six weeks prior to admission his physician treated him with pills, which were said to have reduced the jaundice somewhat. He denied the use of alcohol or drugs.

There was no family history of jaundice. His mother died of carcinoma of the bowel. The past history was noncontributory.

Physical examination disclosed a fairly well-nourished man who was moderately jaundiced. The scleras were deeply jaundiced. The lungs were normal. A soft systolic murmur was audible at the apex of the heart. The abdomen was soft but there was slight resistance to deep palpation in the right upper quadrant. A smooth, hard liver edge was palpable two fingerbreadths below the costal margin.

The blood pressure was 145 systolic, 75 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red-cell count of 3,500,000, with a hemoglobin of 12.5 gm. per 100 cc. and a white-cell count of 10,900, with 73 per cent neutrophils. The urine gave a + test for albumin and +++ test for bile; the sediment was negative. A blood Hinton test was negative. The stools were clay colored, soft, formed and repeatedly guaiac negative. The protein was 7.2 gm., the albumin 4.8 gm., and the globulin 2.4 gm.

er 100 cc. The van den Bergh was 6.8 mg. direct, and 9.8 mg. indirect. The prothrombin time was 32 seconds (normal, 22 seconds), the carbon dioxide combining power 15.3 millimols per liter, the chloride 97.0 milliequiv. per liter, the phosphorus 3.7 mg. per 100 cc., and the phosphatase 15.8 units per 100 cc. A cephalin flocculation test was 0 at 24 and 48°C.

A gastrointestinal series disclosed a normal esophagus, stomach and duodenum. No evidence of encroachment on the stomach or duodenal loop by an extrinsic tumor was observed, and there was no infiltration of the duodenum. A film of the right upper quadrant showed no evidence of gallstones. Chest x-rays were negative.

On the sixth day the patient began to run a spiking temperature, ranging from 100 to 103°F. This continued for six days and then subsided completely. The white-cell count varied from 8000 to 12,000. An occasional stool was light brown but most of them were clay colored. On the tenth day duodenal drainage yielded amber fluid containing a few white cells and calcium bilirubin crystals. He continued to be deeply jaundiced.

After preoperative preparation, including saline glucose infusions and water-soluble vitamin K, an operation was performed on the nineteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. EDWARD HAMLIN, JR.: The first question to decide is whether or not we are dealing with true obstruction or intrahepatic jaundice. The evidence, particularly the laboratory findings and the description of the liver on palpation, is strongly suggestive of obstructive jaundice. Is the obstruction on the basis of tumor or of stone? In favor of the former is the age of the patient and the history of gradual painless onset. Incidentally, the severe itching might be interpreted in favor of obstructive as opposed to intrahepatic jaundice.

The two episodes of lower abdominal crampy pain, although they might be attributed to biliary colic, are so atypical that it is unwise to consider them as such. The laboratory findings enable one to say only that the patient was moderately jaundiced, had a mild anemia of the secondary type and had no evidence of liver damage as evidenced by globulin tests, both as regards amount and qualitatively (cephalin flocculation test). One would like to know whether the low carbon dioxide combining power was a reflection of abnormal carbohydrate metabolism.

The x-ray examination does not help at all, although occasionally a careful study of the duodenum is of great assistance in such cases.

One must attribute the six days of spiking temperature to cholangitis or to infection entirely unrelated to the primary disease. As Dr. Arthur W. Allen has often pointed out, an occasional brown stool in a series of completely clay-colored ones is commoner in association with carcinoma in the region of the ampulla than with stone, a fact that is presumably attributable to necrosis and sloughing of the tumor, which allow some bile to escape.

Thus far the evidence has tended to point strongly toward the diagnosis of tumor in the region of the head of the pancreas or of the extrahepatic biliary tract. But someone ordered a duodenal drainage, and the report came back that calcium bilirubin crystals were present. If the observation was made by an experienced man, that single fact outweighs in my mind all the piled-up evidence in favor of tumor. Of course it is conceivable that the patient may have had both stones and tumor; but if one diagnosis is to be made, the presence of calcium bilirubin crystals in the duodenal drainage causes me to make the diagnosis of common-duct stone a heavy favorite.

DR. CLIFFORD C. FRANSEEN: We approached the problem much as Dr. Hamlin did, believing that a tumor in the region of the head of the pancreas could not be excluded. At operation the liver appeared to have undergone moderate cirrhotic changes. The gall bladder was found to be distended and free of stones. The common duct was dilated to between 2.0 and 2.5 cm. in diameter. There was a fairly discrete mass in the head of the pancreas, contiguous to the wall of the duodenum, which felt to be about 3 cm. in diameter. Its consistence was characteristic of carcinoma. Because of the patient's long-standing jaundice, it was thought that a two-stage procedure should be done. Accordingly a cholecystojejunostomy was performed as the first stage.

Fifteen days later the second stage was carried out. The pylorus, the first and second portions of the duodenum, the distal half of the common bile duct and the head of the pancreas were resected en bloc. It had been hoped that the end of the third portion of the duodenum could be sutured over the cut end of the pancreas, but this proved to be mechanically impossible, and attempts to fit a loop of jejunum against the cut end of the pancreas produced such a sharp angulation of the bowel that its function would undoubtedly have been too greatly jeopardized. This was due to the fact that the cut end of the pancreas lay in an extraordinarily deep hole. Exteriorization of the cut end of the pancreas was therefore resorted to by drainage anteriorly. This seemed the most direct route, especially since drainage through the

right flank would have had to pass beneath the cholecystojejunostomy. A posterior Polya gastrojejunostomy was done.

CLINICAL DIAGNOSIS

Common duct stone?
Tumor of head of pancreas?

DR. HAMLIN'S DIAGNOSIS

Common duct stone?
Carcinoma of ampulla?

ANATOMICAL DIAGNOSIS

Adenocarcinoma of common bile duct.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The specimen received in the laboratory consisted of the distal portion of the stomach, about 10 cm. of duodenum and the head of the pancreas with the distal 5 cm. of the common bile duct coursing through it. The proximal half of the bile duct was dilated, measuring 2.5 cm. in circumference, but the distal half was narrowed to a circumference of 0.7 cm. There the mucosa was roughened and covered with grayish-white granular tissue, which histologically proved to be adenocarcinoma. The tumor invaded the wall of the bile duct and also blocked the opening of the pancreatic duct, which opened into the bile duct just above the sphincter of Oddi. The pancreatic duct was slightly dilated.

Dr. Hamlin placed a good deal of weight on the presence of calcium bilirubin crystals in the duodenal drainage specimen. How valuable is this test, Dr. Jones?

DR. CHESTER M. JONES: The diagnostic value of a study of duodenal contents in these cases has been proved by many years' experience. Like every other laboratory test, however, it is subject to exceptions, and therefore must be interpreted in relation to the clinical picture. If a good specimen of duodenal contents is obtained and it is found that the sediment contains moderate or

excessive amounts of calcium bilirubin and cholesterol crystals, then the diagnosis of biliary calculus is reasonably certain. If a fair number or an excessive number of cholesterol crystals are obtained, then the same diagnosis should be reasonably considered. Where, as in this case, the sediment contains only white cells and calcium bilirubin crystals, then a more detailed examination should be made of the duodenal contents for other elements, and it should be correlated with the clinical picture. Prolonged biliary stasis, such as may occur in infectious hepatitis or in a prolonged period of extrahepatic obstruction, may cause a precipitation of calcium bilirubin crystals and the appearance of small masses resembling casts. When a flow of bile is re-established, these elements are found for a few days, the casts consisting of mucus, detritus and bile-stained material. Not infrequently, particularly in infectious hepatitis, groups of bile-stained white cells are also noted. Under circumstances such as this patient experienced, with prolonged jaundice and a subsequent flow of bile, which must have been obtained when a duodenal drainage was performed, the appearance of some calcium bilirubin crystals and some white cells in the stasis bile is not diagnostic, and too much stress must not be laid on it.

DR. FRANSEEN: The patient did well postoperatively until the fourth day, when bilateral ligation of the superficial femoral veins for deep thrombophlebitis had to be done. Drainage of pancreatic juice from the sinus tract was profuse. On the thirteenth day the patient had a small hemorrhage from the tract and on the thirty-first day a second hemorrhage. He died a few hours later.

DR. CASTLEMAN: The postmortem showed that the space previously occupied by the resected head of the pancreas and duodenum was replaced by an abscess cavity filled with purplish necrotic material that had eroded into the sutured end of the common bile duct and also into the main portal vein. The result was the development of a pylephlebitis, with numerous abscesses of the liver.

STARVING EUROPE

THE January 9, 1943, issue of the *British Medical Journal* brings forcibly to one's attention the herculean task of relief in Europe that will face the Allied Nations after the war. Most urgent, of course, will be the provision of food and shelter for the millions still living but rendered destitute and starving by the paternal ministrations of the "master race." After this will come medical care of the sick, social reorganization and, as soon as possible, re-establishment of agriculture and industry.

Efforts are, even now, constantly being made to render what aid is possible to the starving in-

habitants of the conquered nations, but the amount that can be sent and the uncertainty of its getting by so ruthless an enemy render the total results pitifully inadequate. The British Famine Relief Committee has estimated the quantities of dried milk and vitamins needed to save the children of Greece and Belgium, and Sweden has expressed its willingness to carry on this relief. Under the present arrangement 100 tons of powdered milk, in addition to the monthly supply under navicerts of 15,000 tons of wheat, will be and has been dispatched to Greece in Swedish vessels, to be distributed by the International Red Cross.

The need, however, is appalling. In Athens, 100,000 out of 1,000,000 have died of starvation and disease. As early as December, 1941, according to the Athens Welfare Center, 9 out of 10 babies were dying in their first six months because of starvation of their mothers and the lack of milk, practically all the cattle having been slaughtered. From eye-witness accounts: "The children had not even the strength to beg, and some had died as they crouched over a grating; they seemed to be asleep, and hours might pass before their companions realized they were dead. . . . Orphans and abandoned children are found wandering in the streets . . . starving, dirty, pale and thin. . . . They stop at nothing to find a bit to eat, searching among refuse and fighting the dogs for something edible." In June, 1942, in one temporary hospital in Athens, four children were found to a bed. In Belgium, the infant mortality has quadrupled since 1939, with the tuberculosis morbidity increased from 30 to 80 per cent. Thus has the world benefited from that famed *Kultur* of which our adversaries are so proud!

The combined medical and nursing resources of the Allied Nations must also be mobilized, for the apocalyptic horsemen still ride together, and pestilence follows famine as surely as famine follows war. Not only is tuberculosis on the increase but malaria, typhus and the enteric diseases will have to be combated, and scientific nutritional measures put into effect.

The state of so much of the world renders it increasingly imperative that this war be won by the nations that are opposing the slave system of society. After the war, all alliances must be assiduously preserved, for a new world will have to be constructed on the ruins of the old. Friendships must be cultivated, and resources must be husbanded, for there will be desperate need of them both.

A SEMICENTENNIAL OF OSLER'S PRINCIPLES AND PRACTICE OF MEDICINE

FIFTY years ago last year, in 1892, there was published by the D. Appleton and Company of New York, William Osler's *Principles and Practice of Medicine*, intended for the use of practitioners and students of medicine. The appearance of the fourteenth edition in 1942, rewritten in large part by Henry A. Christian but still based on the sturdy design and structure established by Osler, marks the vigor and soundness of this book, one of the great contributions to medical literature. As Cushing pointed out in his *Life of Osler*, the work began seven or eight years before the actual publishing of the first edition. Osler, during those years, wrote various editorials for the *Medical News*, of Philadelphia, and thus kept himself in touch with the new and important ideas in medicine, and when he composed his medical masterpiece, he did it with a thoroughness and a sureness of touch that were immediately apparent to all his contemporaries. In addition, he wrote in such a readable form that this book immediately superseded all other textbooks of general medicine, and has continued to hold a place in the field for fifty years. It was based on sound pathology plus a wide knowledge of clinical medicine. Its sale was so rapid that the first printing, three thousand copies, was sold out in two months, an unprecedented sale for a book of this type. A few corrections were made in the second printing of the first edition. Subsequently, there have been issued nineteen editions in English (thirteen published in America and six in England), three and

an appendix in Chinese, and one each in French, German and Spanish.

In the Boston Medical Library a section is devoted to the editions of this book, where there are examples of all the editions with many variants, numbering over ninety. The history of this book should some day be written for in it, if successive editions are examined, will be found the history of the advancements in clinical medicine in the last fifty years. The last edition, rewritten by Dr. Christian, is a worthy successor to a long line of previously published volumes. In honor of this semicentennial volume, the *Journal* extends congratulations to both Dr. Christian and the D. Appleton-Century Company.

MEDICAL EPONYM

WILSON'S DISEASE

The essay "Progressive Lenticular Degeneration: A familial nervous disease associated with cirrhosis of the liver" formed part of a thesis by S. A. K. Wilson (1878-1936). The monograph appeared in *Brain* (34: 295-509, 1912), and the following is a quotation from pages 486 and 487:

Progressive lenticular degeneration is a disease of the motor nervous system, occurring in young people and very often familial. It is not congenital or hereditary.

It is progressive and fatal within a varying period: acute cases may last only a few months . . . the average duration of chronic cases is four years.

It is characterized by a definite symptom-complex, whose chief features are: generalized tremor, dysarthria and dysphagia, muscular rigidity and hyper-tonicity, emaciation, spasmodic contractions, contractures, emotionalism. . . .

Although cirrhosis of the liver is constantly found . . . there are no signs of liver disease during life. . . .

The chief pathological feature of the disease is bilateral symmetrical degeneration of the putamen and globus pallidus, in particular the former. . . .

A constant, essential and, in all probability, primary feature of the pathology of the disease is cirrhosis of the liver, not syphilitic or alcoholic.

R. W. B.

MASSACHUSETTS MEDICAL SOCIETY DEATHS

ABBE—ELIZABETH M. ABBE, M.D., of Roxbury, died January 18. She was in her sixty-ninth year.

Dr. Abbe received her degree from Tufts College Medical School in 1909. She was a member of the Massachusetts Medical Society and the American Medical Association.

FRANK—**MORRIS FRANK, MD**, of Roxbury, died June 17. He was in his fifty seventh year.

He received his degree from Harvard Medical School in 1911. He was a counselor of the Massachusetts Medical Society, a member of the American Medical Association and the American Association of School Physicians. He was a staff member of the Beth Israel Hospital, the Jewish Memorial Hospital and the Washingtonian Hospital. His widow and a son survive.

MERCHANT—**RAYMOND F. MERCHANT, MD**, of Vineyard Haven, died June 7. He was in his forty second year.

Dr. Merchant received his degree from Middlesex University College of Medicine. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow survives.

PHILLIPS—**MAJOR ROBERT T. PHILLIPS**, former Boston physician, died in a Japanese prison camp in the Philippines. He was in his forty second year.

Dr. Phillips graduated from Bowdoin College in 1924 and Tufts College Medical School in 1932, and afterward served on the staff of the Boston City Hospital. He was called into active service from the Medical Reserve Corps several months before the attack on Pearl Harbor and was at Manila when war was declared, following the evacuation of Manila he presumably went to Batavia. Dr. Phillips was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and four children survive, as well as his twin brother, Dr. Richard B. Phillips.

WRIGHT—**ALLEN H. WRIGHT, MD**, of East North field, died June 17. He was in his sixty sixth year.

Dr. Wright received his degree from the University of Maryland School of Medicine and College of Physicians and Surgeons in 1906. He was a member of the Massachusetts Medical Society and the American Medical Association.

His widow and two daughters survive.

MISCELLANY

BREAKDOWN IN EARLY TUBERCULOSIS

Too often we substitute words for action. We repeat the same soul satisfying phrases until we endow them with a magic and totally undeserved quality of being able to accomplish miracles. Miracles do not just happen. What look like miracles generally turn out to be the result of careful planning, devotion to sound principles and an unlimited amount of tenacity and hard work. The early discovery of pulmonary tuberculosis, by which is meant discovery of the disease in a minimal stage, is an empty accomplishment unless it can be followed by thorough treatment without delay. The following abstract of a recent paper (Stein, S. C. Breakdown in early tuberculosis. *Pub Health Nursing* 35:140-142, 1943) is pertinent.

* * *

The prevalent opinion that the finding of active tuberculosis in a minimal stage warrants an excellent prognosis is true only when adequate treatment follows at once. Many of the favorable reports have come from sanatoriums where the outlook on minimal pulmonary tuber-

culosis is not the same as that in the clinics at the time of the early diagnosis.

In sanatoriums the number of minimal cases has not increased in direct proportion to the number of cases found on the outside. Failure to see and follow many diagnosed cases may explain this impression. Some patients who reach the sanatorium with minimal disease may show no unfavorable progression even though weeks or months elapsed between the time of discovery and the beginning of institutional care. These are the more resistant cases. Conversely, a significant number of patients found in surveys, and particularly among those in contact with sputum positive tuberculosis, demonstrate low resistance and a rapid progression of their disease before sanatorium care is finally sought and obtained.

In the Henry Phipps Clinic, Philadelphia, Pennsylvania, even though the serious potentialities of minimal pulmonary tuberculosis are recognized and the physicians and nurses endeavor earnestly and persistently to overcome obstacles that prevent adequate care of these patients, results are astonishingly poor. A study of patients with minimal lesions has revealed that almost half developed progressive disease—true of both white and colored patients. Mortality figures were 25 per cent for the colored and 6 per cent for the white patients. Only one of the cases that died had obtained sanatorium care, and then only when the disease had progressed to an advanced stage.

What causes the poor results? The dominant factors will, largely, be applicable to most localities.

First, the diagnosis. It is universally accepted that the x-ray is the most efficient method. Visualizing the minimal lesion is not difficult but evaluation of its status is not so simple or foolproof. There are three categories: lesions whose appearance indicates active, unstable disease; lesions considered of doubtful significance; and lesions whose x-ray appearance suggests that complete healing has occurred.

Determination of the character of a lesion is based to a large extent on experience with previous similar lesions observed over long periods. Interpreting the objective film is a distinctly subjective procedure and is of prime importance since it influences recommendations for treatment. Many chest experts advocate the follow up of contact cases for a period of at least two years after known exposure ceases. It is obviously necessary to follow for a similar period these cases in the second and third categories mentioned to ensure their diagnosis of stability.

Of the nearly 50 per cent of the institutes' minimal cases that showed progression of the disease, 86 per cent developed extension within the first year, the remainder within three years. Serial x-ray studies enable the clinician to determine at the earliest time those cases in which the original estimate of the lesion's stability was faulty.

Following the diagnosis a strong rapport between physician, nurse and patient is essential. The psychologic reactions of the patient to his disease and its treatment depend on the confidence he has in his medical advisers. It is difficult to convince a symptomless patient, often one who was found by survey means and not by his own seeking, to accept such 'drastic treatment as absolute bed rest. He often scoffs at the diagnosis, claims to feel well and refuses to co-operate.

People in contact with sputum positive tuberculosis may submit to examination merely for the comfort of being told they are free of the disease. When their hopes are

dashed and they are confronted with their own unsuspected trouble, they may turn antagonistic and refuse to accept advice.

Again, society has done little to solve the problem of the family head who must leave behind a situation of destitution for the ones he loves by accepting treatment that must necessarily be a prolonged hospitalization.

Assuming that all these deterrents to treatment have been removed, the actual obtaining of hospital care is in many communities still a great problem, growing greater owing to wartime shortages of materials and personnel. Institutions that require positive sputum before admitting a patient are inviting dangerous progression before making available the badly needed bed. The tendency to regard minimal cases lightly and to treat them insufficiently is far too prevalent and often leads to inexcusable relapses. Reliance on the standards of twenty years ago, which call for dependence on physical signs, to determine the stability of lesions defeats the whole purpose of early-diagnosis surveys, since the case without clinical manifestations will receive neglect instead of the treatment and close supervision it deserves.

Early diagnosis is meaningless unless it leads at once to intelligent handling, prompt care and adequate follow-up, with eventual recovery and maximum rehabilitation the goal. — Reprinted from *Tuberculosis Abstracts* (July, 1943).

BOOK REVIEWS

Textbook of Gynecology. By Arthur H. Curtis, M.D. Fourth edition. 8°, cloth, 723 pp., with 401 illustrations. Philadelphia and London: W. B. Saunders Company, 1942. \$8.00.

The fourth edition of Curtis's textbook is a thorough revision of an already excellent book. Not only has the subject matter been brought up to date, but many improvements and additions have been made.

The first 78 pages are devoted to the anatomy of the female pelvis and perineum. This section is a masterpiece and covers the subject thoroughly. The descriptions are clear, and there are many superb illustrations by Tom Jones.

On this foundation the author proceeds to cover the entire field of gynecology in a competent, complete and yet concise manner. Dr. Curtis is a genius at the difficult art of clear and succinct writing. There is no unnecessary verbiage to confuse and weary the reader. Not only medical students but practitioners will find this book an excellent review of the field, and even specialists will enjoy its lucid expositions.

The section on endocrine is rational and intelligent. Proper emphasis is placed on the sulfa drugs in the treatment of gonorrhea and other infections. Conservative treatment is stressed.

The discussion of tumors is extremely well done. Of special note is the statement that "radium treatment is more radical in its effects than surgical removal." Dr. Curtis quotes Robert Meyer as saying that it is impossible to classify ovarian tumors, and then classifies them. Like all such classifications, it leaves something to be desired. Furthermore, the relative frequency of the various types of tumors might well have been emphasized. Dr. Curtis seems a little too conservative in frowning on resection of the ovary. The reviewer believes that the operation is of value in certain cases. Moreover, a waiting policy, when confronted with a sizable ovarian tumor, may diminish the chance of recovery in malignancy, since operation before spread of the malignancy is as important with ovarian neoplasms as it is elsewhere. Pre-operative differentiation is difficult, and if doubt exists, the reviewer is of the opinion that the patient should be given the benefit of that doubt.

The author's discussion of displacements and relaxation is excellent. It is based on his own work and shows the touch of the master. From the detailed instructions concerning the proper method of inserting a pessary to the descriptions of operative technics, this section is a model of medical writing.

There is no mention of vein ligation in the discussion of femoral thrombosis and pulmonary embolism. The treatment of "milk leg" by injection of the lumbar sympathetic nerves is also ignored. Since these constitute important advances in the treatment of not too rare complications of gynecologic surgery, they should certainly be mentioned.

Throughout the book Dr. Curtis's approach is sane, sound and conservative. As Lincoln might have said, "Anyone who wants a textbook on gynecology will find this a good book."

The Anatomy of the Nervous System from the Standpoint of Development and Function. By Stephen W. Ranson, M.D., Ph.D. Seventh edition. 4°, cloth, 520 pp., with 408 illustrations. Philadelphia and London: W. B. Saunders Company, 1943. \$6.50.

The death of the author of this book was a great loss to neurology and America. He had established himself as a leader in the field of anatomy of the nervous system, as well as in neurologic research. Fortunately, the seventh edition was completed before Dr. Ranson's death, and the book is in the form that he would have desired to see it.

This text has become a standard work on the subject, gradually expanding through its numerous editions since 1920. The subject is presented in a dynamic manner, with emphasis laid on the developmental and functional significance of structure. In this edition certain chapters have been rewritten, particularly those on the sympathetic nervous system. The book has been slightly lengthened, and each page was carefully gone over by the author and his colleagues. Many suggestions from neuroanatomists have been incorporated into this edition, and the section on physiology has been considerably expanded. The volume, therefore, replaces previous editions as a text of outstanding value.

NUMBER 4

OLIVER WENDELL HOLMES AND PUERPERAL FEVER

FREDERICK C. IRVING, M.D.

BOSTON

ON THE evening of February 13, one hundred years ago, the speaker before the Boston Society for Medical Improvement had reached the conclusion of his essay "The Contagiousness of Puerperal Fever." He was a small, frail man just about to enter middle age—for he was thirty-four years old—and his name was Oliver Wendell Holmes. His face had lost much of its customary expression of humorous benignity, his sensitive mouth was firm, and the usual twinkle was gone from his eyes; for never had he been so much in earnest. He said:

There is no tone deep enough for regret, and no voice loud enough for warning. The woman about to become a mother, or with a newborn infant upon her bosom, should be the object of trembling care and sympathy wherever she bears her tender burden or stretches her aching limbs. The very outcast of the streets has pity upon her sister in degradation when the seal of promised maternity is impressed upon her. The remorseless vengeance of the law, brought down upon its victim by machinery as sure as destiny, is arrested in its fall at a word which reveals a transient claim for mercy. The solemn prayer of the liturgy singles out her sorrows from the multiplied trials of life, to plead for her in the hour of peril. God forbid that any member of the profession to which she trusts her life, double precious at that eventful period, should hazard it negligently, unadvisably or selfishly!

You need no aid from me to place America's most charming writer in the world of letters, but perhaps you will permit me to recall his position in the Boston medicine of his day and to remind you of his contribution to the arrest of the fever, some pestilence that had needlessly destroyed the

lives of so many women in childbirth. And perhaps, also, you will allow me to express, however imperfectly, the peculiar affection that his memory inspires in all Boston doctors, and in every student in Harvard Medical School. As professor of anatomy, he evoked a legend that is as fresh today as if he had just bade his final class farewell, and, clutching silently its gift—a silver loving cup—had descended for the last time those thirty-two well worn steps that he had climbed for five and thirty years to instruct, amuse, and delight two generations of his pupils.

When Holmes read his paper on puerperal fever his medical contemporaries knew him as a witty dinner companion, the author of a volume of facile and melodious verse, a well trained and intelligent physician, and a none too successful practitioner. On graduation from Harvard College, after a brief and boring experience with the law, he entered Harvard Medical School, or the Massachusetts Medical College, as it was then called. In 1833 he left medical school temporarily and went to Europe where he spent a little over two years at the University of Paris, then in a position of unchallenged pre-eminence. The great Louis, who originated the statistical study of disease, taught there in those days, as did such other famous men as Dupuytren, Lisfranc, and Velpeau. Of Baron Larrey, the chief surgeon of the Grande Armée, he¹ said, "To go around the Hôtel des Invalides with Larrey was to live over the campaigns of Napoleon, to look on the sun of Austerlitz, to hear the cannons of Marengo, to struggle with the icy waters of the Beresina, to shiver in the snows of the Russian retreat, and to gaze through the battle smoke upon the last charge of the red lancers on the redder field of Waterloo." There, also, he encountered Ricord, who first dis-

¹Tr. cited by citation before the Brooklyn Gynecological Society, May 1943.

²William Lambert Richardson, Professor of Obstetrics, Harvard Medical School, visiting obstetrician, Boston Lying-in Hospital.

tinguished between gonorrhea and syphilis and who had so little faith in morality that Holmes called him "the Voltaire of pelvic literature . . . who would have submitted Diana to treatment with his mineral specifics and would have ordered a course of blue pills for the Vestal Virgins."

Holmes returned to Boston in 1835, received his M.D. from Harvard in 1836, and immediately began practice. He won the Boylston Prize in 1836 and 1837, on the first occasion with an essay "The Indigenous Intermittent Fever of New England,"³ — malaria — which is a medical classic. In 1838 he was appointed professor of anatomy at Dartmouth Medical School and held that chair for two years. With Jacob Bigelow he edited in 1839 the American edition of Marshall Hall's *Theory and Practice of Medicine*, and three years later he published his essay "Homeopathy and its Kindred Delusions,"³ wherein he demolished by *reductio ad absurdum* the doctrines of infinitesimal dosage and *similia similibus curantur*. He was well established in Boston also as a teacher of medicine, for in 1838 with Jacob Bigelow, Edward Reynolds, and D. Humphreys Storer he founded the Tremont Street Medical School and taught auscultation and percussion, newly imported from Europe, and microscopic anatomy, another novelty in America. So successful was this school, which later gave summer courses to Harvard medical students, and so practical was its clinical teaching, that the university absorbed it in 1847. It is evident, therefore, that by 1843 Holmes not only had behind him an excellent professional education, but also had attained considerable importance as a medical writer and teacher.

When Holmes read his essay on puerperal fever, it is most unlikely that he had ever encountered in his own practice a case of that disease. Moreover, there was no large obstetric clinic in Boston where he could have studied it. At the Boston Lying-in Hospital, then housed in a small building on Washington Street, there were only about twenty-five women delivered each year—not enough material for even a small epidemic. Aside from the city almshouse, known euphemistically as the House of Industry, that was the only hospital where pregnant women were admitted. His interest in puerperal fever, therefore, must have been aroused in some other way. If we read, as Cutter did, the minutes of the Boston Society for Medical Improvement for the preceding fall, we find reports of two doctors and a medical student who had acquired infected hands at autopsies performed on two women dead of puerperal fever. The student and one of the doctors died; the other recovered after a long illness. At that time, also, there were small scattered epidemics in Bos-

ton and the neighboring towns, and a number of these cases had occurred successively in the practices of individual doctors. Such circumstances had led Dr. J. B. S. Jackson⁴ to ask "the opinion of the Society as to the Contagion of Puerperal Fever, and the probability of Physicians communicating it from one patient to another." This suggestion, and these cases occurring in the practices of his colleagues, led Holmes, who had a broad knowledge of medical literature, to quote the authorities of the past. Charles White,⁵ of Manchester, England, said he believed—like most of his predecessors and many of his contemporaries—that childbed fever resulted from retention of the lochia. In 1773, to encourage its escape, he invented "postural drainage," and he devised a jointed bed operated by a ratchet that was exactly like those we see today in every hospital ward; he also constructed a reclining chair to serve the same purpose when the patient got up. Moreover, White was the first to demand cleanliness in the lying-in chamber and to isolate infected patients from those who were well. In 1783, Pouteau,⁶ Holmes noted, had detected the association of childbed fever with erysipelas, as had Robert Ceely⁷ in 1831 and Thomas Nunnelle⁸ in 1841. Alexander Gordon⁹ had made in 1795 the first epidemiologic study of the disease, using as the basis an outbreak that had occurred in his city of Aberdeen; and he confessed to his great chagrin that in some cases he must have carried the contagion from one patient to another. Thomas Denman was well known to all who practiced midwifery. His tiny book of obstetrical aphorisms,¹⁰ published at the turn of the nineteenth century, reposed in the tail-coat pocket of almost every British and American doctor, to be withdrawn and consulted secretly behind the woodshed when one was in a tight place. Denman¹¹ also said in 1801 that the disease might be carried from patient to patient, and he pointed out that foul bed linen and dressings might be the means by which this was effected. Finally, Holmes quoted Sir Thomas Watson,¹² his contemporary and the most distinguished English physician of his day, who only the year before had written: "Indeed, I believe that these cases of puerperal fever occurring in succession to the same practitioner are something more than ordinary contagion, operating through the medium of a tainted atmosphere. I believe them to be instances of direct inoculation."

Thus armed with the recent experiences of his colleagues and with the evidence drawn from his reading, Holmes announced his conviction that puerperal fever was carried from one patient to another, and that the person who conveyed the contagion was usually the physician or the nurse.

He evolved no theories about the nature of the contagion, nor did he speculate about the mode of its transmission. As he said later, "When facts are numerous, and unquestionable and unequivocal in their significance, theory must follow them as best it may, keeping time only with their step, and not go before them, marching to the sound of its own drum and trumpet." He drew up certain rules of guidance. These were: no doctor practicing midwifery must take an active part in an autopsy on a woman dying of puerperal fever; if, however, he should be present at such an autopsy, even though he did not touch the tissues, he must bathe thoroughly, change all his clothes, and allow twenty-four hours to pass before attending a woman in labor; he must adopt the same precautions after treating a case of erysipelas—he would be even wiser if he avoided the lying-in chamber as long as this contact existed; if a doctor had a case of puerperal fever, he should consider his next obstetric patient in danger of being infected by him; if two cases occurred in his practice, he must give up obstetrics for at least a month; and if he had three cases, he must consider them *prima-facie* evidence that he was responsible for the infection. Moreover, he warned, the doctor must inquire diligently concerning the nurses and attendants who take care of his patients; if they had been in contact with cases of childbed fever, they must not be employed. Finally he said, "A private pestilence in the practice of a physician is not a misfortune but a crime."

All of us who love Holmes could conceive no greater satisfaction than to hail him as the discoverer of the contagious nature of puerperal fever. But here, as so many times, cold facts and the printed word prevent, for he was not its discoverer, nor—as we have seen by the array of authorities he himself quoted to prove his point—did he ever claim to be. But his was the first voice raised in America to drive home this appalling truth; and never, in the whole history of medicine, did any advocate plead his case with greater eloquence or with more conviction.

Holmes's essay appeared in the April, 1843, issue of the *New England Quarterly Journal of Medicine and Surgery*, an obscure periodical that soon ceased publication. At the request of his friends, however, he secured reprints; and some of them eventually fell into the hands of Charles D. Meigs and Hugh L. Hodge, both of Philadelphia; had not this happened, the world might then have profited little by his essay, for it would have remained hidden in the files of a defunct medical journal. Thereupon both Meigs and Hodge expressed their unequivocal disapproval of Holmes, his essay, and the idea that doctors could carry in-

fection from one patient to another. Hodge¹³ was courteous and moderate in his statements, but Meigs¹⁴ attacked the Bostonian in a most insulting fashion. "I prefer," said he sanctimoniously, "to attribute these cases to accident or Providence, of which I can form a conception, than to contagion, of which I cannot form any clear idea." From the eminence of his chair at the Jefferson Medical School he glared down at the little New England upstart, and he characterized the statements of Holmes and of those who held the same beliefs as the "jejune and fizenless dreamings of sophomore writers."

To defend his position, Holmes¹⁵ republished his essay in 1855 under the title "Puerperal Fever as a Private Pestilence," and to it he added certain remarks. He was a kindly man and the soul of courtesy, but it is a pleasure to find that when he tried his hand at polite invective he was good at that, too. In noting that his opponents were professors in two of the country's leading medical schools, and that as such their opinions, although wrong, would have a profound effect on their students, he said that these young men "naturally have faith in their instructors, turning to them for truth and taking what they might choose to give them; babes in knowledge, not yet able to tell the breast from the bottle, pumping away for the milk of truth at all that offers, were it nothing better than a professor's shrivelled forefinger."

Charles Delucena Meigs was one of the most remarkable men in the history of American medicine, not because of anything that he personally accomplished—for a careful search of his works reveals not a single contribution to the healing art—but because he was wrong so often on such important matters and in such a violent manner. He was against everything new and he was against everyone who thought that anything new was good. He¹⁶ quarreled with Channing and Simpson over anesthesia in childbirth, and he¹⁷ berated McDowell when he removed ovarian cysts and thereby saved his patients' lives. Yet the world owes him some gratitude, for had he not assailed Holmes in such a bitter fashion the little doctor might never have returned to the attack.

What, in the history of puerperal fever, is the relation between Holmes and Semmelweis? As regards the transmission of ideas, there is no continuity whatever; for Semmelweis, who began his work three years after Holmes's essay, had never heard of the American. Semmelweis was appointed assistant professor in the *Frauenklinik* of the *Allgemeine Krankenhaus* in Vienna in 1846. Soon after assuming his duties he found that the mortality from puerperal fever among the patients delivered by the students was over

twice that among those under the care of the midwives. He also noted that few women died who had been delivered before they entered the hospital or who had entered in premature labor: the common factor was that none of these patients were examined. At about this time his friend Kolletscha died from a wound received in making an autopsy, and he found the same changes in Kolletscha's body as those that he had seen in women who had died of puerperal fever. He thereupon forbade students to come directly from the autopsy or dissecting rooms to deliver women in the clinic, and he ordered that everyone who examined a patient in labor should wash his hands with liquid chlorine or chlorinated lime. He was the first, therefore, to insist on disinfection of the hands at the time of labor; both Watson and Holmes had gone no farther than to advise it when leaving a case, so that one might avoid carrying contagion to the next patient. Immediately there was an improvement, and during the next year the death rate was cut in half.

In 1847 Semmelweis's results were published by Hebra,⁴ his colleague, who followed with a second article in 1849.⁴ It was not until 1861, however, that Semmelweis's book, *The Cause, Concept and Prophylaxis of Puerperal Fever*, appeared. Whatever advantage there is in priority, therefore, belongs to Holmes; although neither he nor Semmelweis, as is clearly shown by the authorities that the Bostonian quoted, was the first to advance the theory that childbed fever was contagious. As long before as 1694, Phillipe Peu,¹⁷ of Paris, had said, "Putrid effluvia, exhaling from wounded men, brought on a fever which killed a great many childbed women who lay in the same hospital"; and he added, "Are not the putrid effluvia, arising from the lochial discharges in lying-in hospitals, capable of producing the same disease?" To Holmes, also, goes the credit for greater eloquence and vigor of expression; his essay is one of the literary masterpieces of medicine. But his premises were based entirely on the experiences of others; he had no personal knowledge of the disease. On the other hand, Semmelweis's conclusions sprang from his own clinical experiments; there was no need to summon other evidence; indeed, the fact that he knew nothing of the existing literature on puerperal fever adds, if anything, even more to his honors.

After Holmes and Semmelweis about forty years went by before epidemic puerperal fever was finally checked. In America the reactionary influence of Meigs and Hodge, and in Europe that of Semmelweis's opponents—led by Scanzoni,⁴ of Prague—continued to cost the lives of countless women. There was more respect in those days for

academic authority, there were fewer professors, and they were vastly more impressive; their *ex cathedra* statements had all the authenticity of gospel. Moreover, if the contagion was really carried from patient to patient, no one had yet demonstrated its nature or how it was conveyed, for the science of bacteriology did not then exist. In 1865, however, Lister,¹⁸ inspired by Pasteur's discovery that micro-organisms caused fermentation and putrefaction, introduced the principle of antisepsis. To him obstetrics is as much indebted as is general surgery, for nine years later Bischoff,¹⁹ of Basle, impressed by what he had seen in England, applied Lister's methods to women at delivery. Further steps toward the control of puerperal fever followed a logical sequence; in 1878 Koch²⁰ showed that bacteria exist on every unsterilized surface, and the next year Pasteur²¹ discovered that the streptococcus caused the most virulent form of the disease. Using the antiseptic technic that followed such progress, Breisky,²² of Prague, was able in 1882 to report that he had delivered eleven hundred women in succession without a single death—then an unheard of record.

Garrigues,²³ the first to introduce antiseptic obstetrics into America, reduced the death rate at the New York Maternity in 1885 from one in sixteen to one in seventy-two; and using the same methods his friend, Richardson,²⁴ of the Boston Lying-in Hospital, reported that during the following year no woman had died of puerperal fever, although for some time the mortality had been one in twenty. Simultaneously occurred the development of surgical asepsis, which was introduced by von Bergmann²⁵ in 1882. Finally, in 1894, came the publication of Tarnier's book, *De l'asepsie et de l'antisepsie en obstétrique*, which, except for a few minor points, described an aseptic regimen that is as sound today as it was fifty years ago.

As we bid farewell to puerperal fever and to Dr. Oliver Wendell Holmes, we are still puzzled by the question, Why did he abandon the practice of medicine? A man of his intellect and professional training, possessing his knowledge of humanity and his store of ready sympathy, seemed blessed with every essential quality that a good doctor requires. Perhaps he was too tenderhearted, for he was always distressed by suffering in any creature. Possibly, also, the fact that he wrote verses caused his patients to distrust him as a doctor. They forgot that the same god held sway over poetry and medicine; nor were they mindful of the fact that one might woo Euterpe and worship Aesculapius, and still be counted faithful to Apollo. Of course, Mr. Emerson, of Concord, was a poet, although at times he was a

little difficult to understand; so was dear Mr. Longfellow, of Cambridge, who wrote those lovely lines about the blacksmith and the chestnut tree; but, then, neither of them was a doctor. New Englanders in those days liked their medical men to be dignified; if they were portentous, pontifical, and prolix, so much the better. It may have been that Holmes's gay, untrameled spirit seemed out of place in the sickroom; it is also possible that the refined ribaldry that colored some of his utterances disquieted his patients. A man²⁶ who had referred in one of his lectures to the old anatomical plates of Spigelius as those "in which lovely ladies display their viscera with a coquettish grace, implying that it is rather a pleasure than otherwise to show the lace-like omentum and hold up their appendices epiploicae as if they were saving. 'These are our jewels,'" might well be too light minded to be intrusted with the care of those who were seriously ill. Also, it was rumored that he had once defecated woman as a "constipated biped with a pain in the back."

The definite break with practice came in 1857, when the *Atlantic Monthly* was founded and "The Autocrat of the Breakfast Table" began its appearance in serial form. From then on, aside from his lectures at the medical school, which continued until his retirement in 1882, he was primarily a man of letters. Perhaps, after all, the real answer lay in a remark he²⁷ made toward the end of his life about his medical friends: "I hope that they are not ashamed of me and do not reproach me for choosing the flowery path of very light literature rather than to chain myself to the heavy tasks of medical practice." And so it happened that Oliver Wendell Holmes is known to history as a poet, essayist, and philosopher, for there are few besides physicians who remember his part in casting out the evil spirit that in those days haunted the lying-in chamber; and so it happened

also that although he is by no means Boston's most famous doctor, he is, without a doubt, the most famous Bostonian who ever practiced medicine.

CARE OF THE VICTIMS OF THE COCOANUT GROVE FIRE AT THE MASSACHUSETTS GENERAL HOSPITAL*

OLIVER COPE, M.D.†

BOSTON

THE Massachusetts General Hospital has recently passed through a most instructive experience. On Saturday evening, November 28, 1942, the Cocoanut Grove, a Boston night club, caught on fire. As a result, 491 men and women lost their lives. During the two hours following the onset of the fire, 114 casualties were brought to the Massachusetts General Hospital. The majority of these were dead on arrival, many survived only a few minutes, but 39 lived and were treated.

The patients arrived in various states. A few came in taxis and walked into the hospital. Most were brought by ambulance on a stretcher. Some were carried in unconscious with no visible burns and died a few minutes after entry. A number were competent and lucid, many were maniacal. The surface burns of the early arrivals were limited to the head and hands; the clothing was but little damaged. Nearly all were coughing; some had labored breathing. Eyes, nostrils and mouth were often burned. Both the mucous membranes and burned surfaces of several patients were cherry red in color, indicating some degree of carbon monoxide poisoning. It was obvious almost at once that we were dealing with something more than the problem of burned skin; a severe impairment of respiration also existed. The possibility that there was pulmonary damage due to an explosion was considered until a few victims arrived who were able to give an account of the fire. It was then clear that no explosion had occurred but that suffocating fumes, in addition to flames and hot air, had been inhaled. An increasing proportion of the late arrivals were extensively burned and unconscious; their clothing was charred and soaking wet.

By this time the general pattern of the injuries sustained was established. The surface burns involved the head and hands, and in the open areas inadequately covered by clothing such as the neck, back, arms and legs. The arms were sooty and shaggy from ruptured blebs. In some the cherry-red color of the deeper burn

tissue was vivid. Although burns of the upper respiratory passages were absent in many, signs of pulmonary damage were present in nearly all. There were no fractures in spite of the panic at the fire.

Had this not been a war year, the staff of the hospital would have been overwhelmed by many victims. As it was, the hospital in many ways was prepared to receive them.

The hospital's preparedness was due to two of its war activities. First, since Pearl Harbor, the staff had been organized into teams to meet possible bombing disasters; drills had been held. Second, in two research projects, under the auspices of the Office of Scientific Research and Development, the problems of burns had been under investigation in the laboratory and clinic for nearly a year. Many of the staff had taken part in this research program. Newer modes of therapy had been appraised, and finally when a treatment for burns had been selected for use in a disaster the staff was well aware of its use and purpose.

The importance of anticipating a disaster cannot be overemphasized. The casualties reached the hospital on an average of one every fifty seconds. It was necessary to dispose immediately of the dead in order to have room to care for the living. Four medical interns, working in pairs, were stationed at the admitting door to sort out the dead who were taken along one corridor to a temporary morgue. The living were deposited, still on the stretchers, in the rooms and along the corridors of the Emergency Ward. Nurses and interns, usually in groups of four, were assigned to each casualty.

A room of the Emergency Ward had long before been set aside as a storeroom for emergency supplies. Wooden sawhorses were at hand to support the stretchers on. Sets for intravenous injection, sterile goods and ointment, enough to care for two hundred burned casualties, were immediately available.

The hour of the accident was fortunate in that the victims were arriving at the hospital at the time of the evening shift of nurses. Those nurses who were just coming off duty swarmed down to the Emergency Ward to aid those called from duty elsewhere in the hospital. The resident sta-

Assistant professor of surgery, Harvard Medical School; associate visiting surgeon, Massachusetts General Hospital.

of eighty interns and residents were nearly all immediately available. From outside the hospital, medical students, nurses, nurses' aids and college students volunteered in numbers. Members of the nonresident visiting staff assigned to emergency duty, and technicians, were called by the telephone operators. Having at hand classified lists of the required personnel is imperative in such emergencies.

At first the emergency floor was cleared of all other patients. When it was suspected that the casualties might outnumber the bed capacity of the Emergency Ward, one entire floor of the surgical building accommodating forty patients was evacuated according to previous arrangement and set aside as an isolation ward. The former inhabitants of this floor were fitted into vacant places in other wards throughout the hospital. Subsequently a second floor in the surgical building was cleared, but was not needed.

The concentration of the casualties in one area, rather than their dispersal throughout the hospital, has merit. Not only was strict isolation against organisms of the respiratory tract immediately possible, but better supervision of the care of shock and anoxia was permitted. Emergency quarters hastily fitted up in corridors, garrets or cellars have not the facilities of running water, suction, piped oxygen and electric outlets so necessary for the care of the sick.

The treatment of most of the patients was begun while they were still on the stretchers in the Emergency Ward. After they had received an injection of morphine almost at the entrance, their burned surfaces were covered with sterile towels and intravenous fluids were started. The patients were undressed as they were transferred to beds and were wheeled in the beds from the Emergency Ward directly to the isolation floor. Here the burned surfaces were dressed. Members of the staff, doctors and nurses, were dispatched to this floor to carry on the treatment. The resuscitation squad assembled all the anesthesia machines in the hospital for oxygen therapy. By the time the last of the patients was transferred, the entire staff was working on the isolation floor. The patients were divided into groups of four and attended by members of the visiting staff, residents, interns, nurses and students. The responsible staff members of the burn and resuscitation squads acted as consultants for all the groups.

Within three hours of the time of the fire, all 39 patients were settled on the one floor and were receiving, when needed, oxygen for anoxia and plasma intravenously for shock, their surface burns having been protected by the permanent dressings.

The expeditious handling of these casualties was, of course, made possible by an adequate number of doctors and nurses being immediately available, and by the presence of a blood bank and sufficient supplies in the hospital. But the number of the personnel is of secondary importance to having a prearranged plan of action. Without forethought, both in regard to segregation of the patients and the type of therapy to be employed, confusion will reign.

TREATMENT

Prior to the Cocoanut Grove disaster, the members of the staff responsible for the care of burns had advocated a plan of treatment that emphasized primarily the prevention of the threatening complications of any severe burn, shock and infection. Shock can be treated, but it is wise not to allow it to get beyond the impending stage. Infection too can be conquered, but it is safer and more economic to take the pains to guard against it. In general, it had been planned to prevent shock by plasma administration, to guard against infection by strict isolation, aseptic technic and internal chemotherapy and to cover the surface burns with a bland ointment and pressure dressings and not to cleanse or débride them. This plan was adhered to but had to be altered to give precedence to treatment of the lung injuries. Respiratory complications such as the victims of this disaster exhibited had not been reckoned on, and they demanded immediate treatment.

Pulmonary Complications

As the hours passed after the disaster, the succession of pulmonary signs in the patients recalled those encountered in the soldiers of World War I poisoned by phosgene, and were also similar to those seen in the victims of the Cleveland Clinic disaster of 1929. It had been thought that this latter disaster was unique, for with the resulting change in the chemical composition of x-ray film it had not been expected that nitrous gas poisoning would again be encountered in civilian life.

The picture presented by the Cocoanut Grove patients on arrival was startling. The majority were either maniacal or unconscious. At first the mania was mistaken for hysteria aggravated by pain. Subsequently it was realized that in many it was due to anoxia, and that it was comparable to the restlessness and mania encountered in the anoxia of cardiac insufficiency.

Recognition of the part played by each of the three possible causes of such mania—pain, hysteria and anoxia—is important because the rational therapy for each differs.¹ Morphine is the treatment of choice for pain, but it may aggravate hysteria by its cerebral effect, and anoxia by its de-

pression of respiration. Morphine in large doses is a universal recommendation in the treatment of burns, and we employed it routinely, and without proper consideration, on the victims of this disaster. Each patient received $\frac{1}{4}$ gr. immediately on entry. If this did not have a quieting effect, often a second, and occasionally a third, dose was administered. It is probable that the initial dose did not materially depress respiration but did presumably bring comfort by relieving pain. An overdose, however, was certainly given in two or three cases. Respiration ceased in one patient; she was intubated and given artificial respiration with oxygen for a period of five hours, and survived.

Beecher¹ has pointed out that barbiturates given intravenously are better than morphine for the control of hysteria. None were used in these patients because of the large dose or doses of morphine that had already been given.

Obviously, the treatment for mania due to anoxia is the administration of oxygen. To those to whom it could be given it brought relief and quiet. Two patients, however, were so uncontrollable that it was impossible to restrain them to give the oxygen. To one of these, a strong young man, 4 cc. of paraldehyde was given intravenously and it had an immediate quieting effect. The other patient received paraldehyde intramuscularly with a similar effect. It was not given to any other patient, however, because of the fear, perhaps unwarranted, that it might add to the pulmonary irritation, since it is exhaled through the lungs.

Vomiting also added to the difficulty of oxygen administration. A number of the patients, including those who were unconscious, vomited during the early hours after arrival. Constant care had to be taken to prevent aspiration of vomitus. Oxygen therapy would have been carried out more easily in some patients could an intratracheal tube have been passed, but this would have required cocaineization of the pharynx, which was not done because of the fear that vomitus would be aspirated following the loss of sensation.

The anoxia had two causes. The one which played the smaller role was carbon monoxide poisoning. Oxygen with 5 to 7 per cent carbon dioxide was given to the patients with signs of the poisoning. The major cause was pulmonary damage, which prevented the transfer of oxygen from air to blood. The signs of pulmonary damage multiplied hour by hour. Between the third and fifth hours after the accident, when edema of the skin burns became apparent, signs of pulmonary edema were also evident and anoxia was aggravated. Seven patients received oxygen therapy throughout this period, and suction of the upper respiratory tract was needed.

In spite of the edema of the airway and of the lungs, no patients died within the first twelve hours. The mania and vomiting decreased during this initial period and most of the patients subsided into either a coma or deep sleep.

Beginning twelve hours after the disaster, the clinical picture of the respiratory-tract complication assumed an ominous form. Obstruction of the bronchi and large airways menaced life. Seven patients died, all within a period of thirteen to sixty-two hours after the fire and all as a result of anoxia. No patient died after the third day.*

The lungs of the first patient to die had been gradually flooded with progressive edema. Oxygen under pressure was tried without benefit in such cases. The second patient to die, approximately twenty-four hours after the accident, developed acute respiratory failure, apparently due to edema of the larynx. Tracheotomy was done, but without avail. The third patient to die developed similar edema of the larynx, with sudden closure of the glottis. This man was a strapping young Army officer who had walked into the hospital with severe burns of the face, upper respiratory passages and hands. He had been so restless that he could not lie still but insisted on stamping around and waving his hands; such activity probably did not benefit his injured lungs. Within a few hours signs of pulmonary edema were obvious; tracheotomy was of no help. Following insertion of the tube into the trachea, he coughed up a long shred of mucous membrane, indicating severe damage deep in the bronchiolar tree.

The nature of the lung damage became clear after the post-mortem examination of 3 patients. In those patients severely burned about the face there was denudation of the mucous membrane of the nasal passages, mouth and pharynx. There was also obvious damage below the cords of the larynx, with shreds of mucous membrane and exudate heaped up at the upper end of the trachea. The midportion of the trachea was relatively uninvolved, but increased damage was again present at the carina.

The distal part of the bronchial tree showed shreds of edematous, denuded mucous membrane clinging in spots down into the small bronchioles. It was undoubtedly such shreds that several of the patients had coughed up at intervals. Where these shreds were held in situ, signs of occlusion of the bronchus were apparent. Patchy areas of atelectasis alternated with areas of emphysema. In those areas in which obstruction of the bronchus was complete, atelectasis had resulted; where incomplete, sufficient air had passed on inspiration to be trapped and to cause emphysema.

*One patient committed suicide on the forty-second day, a result directly attributable to the disaster.

The burns of the upper air passages were in part due to heat, but it is probable that toxic fumes accounted for some of the pulmonary irritation. One girl with no external visible burn developed moderately severe signs of irritation in the pulmonary tree. The other patients with minor burns of the face and none of the nasal passages, mouth or pharynx developed similar signs of plugging of the bronchioles.

In the patients who survived, this bronchiolar obstruction manifested itself in various ways. Some patients developed typical asthmatic breathing. At times this was relieved by both adrenalin and aminophyllin, and there was therefore undoubtedly an element of bronchiolar spasm, presumably as a result of the inflammation. From day to day, areas of atelectasis alternated with emphysema. Confirmation of the changing physical signs was obtained by frequent roentgenologic examinations. In one patient with no external burns, atelectasis of both lower lobes developed, accompanied by a vital capacity of only 800 cc. Continuous oxygen therapy was necessary for five days. On the ninth day, following postural drainage, she coughed up a large amount of mucocellular material, and the lungs then became filled with air. Throughout this period of atelectasis she was afebrile. There was undoubtedly a plugging of the larger bronchi. No signs of permanent damage have so far resulted.

Tracheotomy was resorted to but was of limited usefulness because the root of the respiratory evil lay distal to the larynx. It was used in 5 cases, only 2 of the patients survived. In one of these the burn of the pharynx was so severe that swallowing was interfered with. Feeding was carried on from the seventh through the sixteenth day by a tube inserted through the nose into the stomach.

The peak of respiratory difficulty passed on the third to the fourth day following the fire. Signs of moisture decreased and the injured air passages opened. Concern for the lives of these patients, however, was not over. Sepsis in the denuded pulmonary tree was still dreaded. Strict isolation of the patients was continued in the effort to exclude contaminating organisms from the respiratory tract, and no clinical or roentgenologic signs of pneumonia occurred. Virulent staphylococci were obtained on culture from the mucocellular material coughed out of the trachea, but no frank abscesses developed. By the end of two weeks the lungs of most of the patients had healed and our vigilance was relaxed. The unhealed lungs of 4 patients, however, kept them in the hospital two weeks longer.

Careful clinical and roentgenographic follow-up of all patients has shown a complete clearing of the lungs in all except 1 patient, who still had an unexpanded area of atelectasis in one lower lobe at one hundred and nineteen days. This patient had only a moderate degree of pulmonary damage and did not require tracheotomy. She was hospitalized for an extended length of time because of her severe surface burns. It is possible that the enforced inactivity was a contributing cause of the residual atelectasis.

Shock

The primary phase of burn shock is generally considered to be neurogenic. An imbalance of the autonomic nervous system results in a relaxation of the vascular tone and therefore in an increase of the capacity of the vascular bed and a drop in blood pressure. Pain is often a cause of this imbalance. Such primary shock was encountered in a few of the patients from the Coconut Grove. One man with moderate burns, who had been soaked by water and thoroughly chilled, had a systolic blood pressure of 80 on arrival. With rest, warmth and morphine his blood pressure promptly rose to normal. But primary shock was confused by anoxia, which tends to raise the blood pressure.

The secondary phase of burn shock comes on more gradually and is caused by the seepage of blood plasma out through the capillaries into the burned area, for the burn creates an abnormal permeability of the walls. Low blood pressure in this phase results from a decrease in the circulating plasma volume and an increase in the viscosity of the blood, the result of hemoconcentration.

The ideal treatment of secondary shock is the constant replacement of plasma as it is lost from the circulation. If this can be done by injection of plasma intravenously, the course of the patient through this phase, which generally lasts for thirty-six hours, will be smooth. If treatment is delayed until the shock state has already been reached, it is more difficult to return the patient's condition to normal. Nearly ideal conditions existed for the prevention of secondary shock in the patients from the Coconut Grove fire. The fire was but a mile from the hospital and all the patients were admitted within two hours of the onset. Adequate quantities of frozen human blood plasma were available in the hospital's own blood bank. The plasma had to be thawed, but to the late-comers was administered intravenously within five minutes of their arrival. Little or no true secondary shock was therefore encountered in any of the patients.

The damage to the parenchyma of the lung, however, created a dilemma so far as the administration of intravenous fluid was concerned. An integral part of the pathologic physiology of a thermal or chemical burn is an increase in capillary permeability in the area burned and its immediate environs. A protein-rich fluid, slightly more dilute than plasma, exudes into the extracellular spaces and out from the tissues where the surface is denuded. Such weeping occurs in burns of the lungs and bronchioles as well as those of the skin, and is responsible not only for the edema of the alveolar and bronchiolar walls but also for the fluid in the alveoli and lumens. The edema and fluid of course cut down the transfer of gases across the alveolar wall, and, when excessive, result in anoxia.

Edema in the burned area may be increased by the intravenous injection of saline or glucose, solutions of small molecules that are freely diffusible through the capillary wall. Such solutions increase blood volume, even transitorily, raise blood pressure, and thereby increase the outflow of the plasma filtrate from the capillaries. Restoration of normal blood concentration and volume by the administration of plasma itself probably also tends to increase the edema of the burned tissues, even though it maintains a normal circulation for the unburned portions of the body. It is possible that if a certain amount of hemoconcentration is allowed to exist, the plasma will seep out of the damaged capillary membrane less readily and edema will be decreased. The blood of the patients with the severe signs of pulmonary damage was allowed to concentrate to some degree. It is not clear whether this hemoconcentration was effective. It was not sufficient to disturb the metabolism of the patient as a whole, since normal kidney and liver functions were maintained.

Surface Burns

The recognition in the last half-century that burn shock is due to plasma loss rather than to absorption of toxin from the burn has created a debate concerning which should be treated first, the shock or the burn. Without proper treatment of shock, the life of the severely burned patient is in jeopardy. To maintain, however, as some still do, that nothing should be done about the burn wound itself until after the treatment of shock has been accomplished is to court trouble.

Neglect of the surface wound means increased bacterial contamination, and contamination means infection. The chief problem of burns is infection, and the most effective way to eliminate infection is to prevent it by covering the wound at the earliest possible opportunity. The importance of

such preventive treatment cannot be overemphasized.

The treatment of the surface wound cannot be divorced from that of shock, for they are interrelated and must go on simultaneously. Infectious toxemia leads to shock, and shock leads to an increased growth of bacteria. Shock from an inadequate circulating blood volume leads to stagnation of blood, particularly in the peripheral tissues, and results in a decrease in oxygen tension. Some organisms, such as certain streptococci, are preferential anaerobes and multiply more rapidly under conditions of anoxia. From the point of view of prevention of infection, therefore, an adequate treatment of shock is imperative, just as is the prompt covering of a burn wound with a protective coating.

One of the drawbacks of the current methods advocated for the treatment of burn wounds is their complexity. It is common practice, both in civilian hospitals and in the armed forces, to débride and cleanse such wounds. Débridement consists of opening all unruptured blebs and cutting away the dead epidermis overlying these blebs and those that have already ruptured. This leaves the dermis exposed, a surface vulnerable to infective organisms. Therefore, such exposed surfaces are gently scrubbed with soap and water or a detergent, and finally rinsed with saline solution. Since such maneuvers may be exquisitely painful, even when deftly performed, anesthesia is often considered necessary. Such débridement and cleansing are conducive to further shock, particularly when accompanied by general anesthesia, and are postponed until the treatment of shock is advanced. Anything that aggravates shock is obviously contraindicated. Such débridement was a necessary preliminary step for the treatment with tannic acid. It has been carried over into other forms of treatment without critical evaluation.

Another relic of the tannic acid ritual, which adds to the complexity of surface treatment, is the two-stage treatment of the burn surface, first-aid and definitive. Débridement and hourly spraying of tannic acid cannot be carried out under first-aid conditions but have to be reserved until operating-room facilities are available. This increased handling is also conducive to shock and is likewise contraindicated.

For several months prior to the disaster the rationale of reducing the treatment of the burn wound to the simplest terms had been explored in the clinic and laboratory of this hospital. Such a simple surface treatment had been tried out, but received its first mass trial on the victims of this fire.

The extent of the surface burn of these patients varied from patches of the mildest first-degree burns to extensive deep burns. The burns of the typical pattern were not extensive but were frequently deep. One third of the patients had burns that were more widespread than the general pattern, and these were deep. Many of the burned areas were grossly clean, others covered with dirt and soot. A number of the patients had been crawling on the floor at the fire or were piled in with the dead. The burns of several were exposed to feces, and many of the patients, dead and living, were incontinent. The eye burns were limited to the lower half of each cornea.

The treatment was carried out as follows: The attendant personnel was carefully masked to prevent the spread of organisms from the upper respiratory tract.* Immediately all exposed burned surfaces were covered with sterile towels. When the patients were undressed and transferred from stretchers to beds, burns of the body were covered by laying sterile sheets on the bed and enfolding the patient in them. On the isolation floor these sterile drapes were removed and the surfaces covered with boric-ointment gauze. The gauze, impregnated with liberal amounts of the ointment and autoclaved, was put on by medical students and interns who wore, in addition to masks, sterile gloves but unsterile gowns. *No débridement and no cleansing of any surface were done.*† Dry sterile gauze was laid over the ointment gauze and pressure bandages were applied to all wounds of the face, scalp and extremities. Sulfathiazole, 5 per cent, in petrolatum was placed in the burned eyes, the lids closed, and the eyes incorporated in the pressure dressings of the face. Only the nostrils and mouth were left uncovered.

As a final but integral part of the surface treatment, 2 gm. of sodium sulfadiazine was injected intravenously into each patient. This was accomplished readily by a technician who injected it into the rubber tubing of the intravenous set, which was already functioning. Subsequent doses of sodium sulfadiazine were given intravenously, or by mouth if the patient could tolerate it.

Such a treatment of surface burns is unorthodox in modern surgery, when one is accustomed to neat wounds. When it was first suggested a year ago that we should not débride a burn wound, this was objected to by those concerned with infection. They believed that all blebs must be opened because otherwise the bacteria harbored in gland crypts would burrow up from the base of the vesicle to infect a fluid that was a fertile anaerobic cul-

ture medium. This objection seemed unreasonable on two counts. In the first place, skin has been shown to have the ability to destroy pathogenic organisms on its surface,²⁻⁴ and it is probable that the gland crypts have the same ability. The only organisms to survive on skin are its natural inhabitants and they are nonpathogenic. These organisms, principally *Staphylococcus albus*, should not lead to an infectious process. In the second place, in the early hours of the burn at least, bleb fluid is in open communication with the extracellular spaces. In 1932, Field, Drinker and White⁵ showed that there is a greatly increased flow of lymph from the area of an experimental burn, suggesting that there is a turnover of fluid in a burn wound. Since the fluid originates in the capillaries, it has the oxygen tension of the blood, and relatively aerobic conditions may well exist in a burn wound until the intercellular spaces become plugged with fibrin. An observation of comparable significance to the increased lymph flow in the dog has often been made in the human being: a débrided burn wound weeps freely, and the protein-rich fluid from the capillaries brings with it a supply of oxygen to the injured tissue.

It remained to be shown in patients with burns that blebs left undébrided did not become infected. Prior to the Coconut Grove disaster, the unruptured blebs of 26 patients, some with several blebs, had been protected from one to fourteen days, after which time the fluid was withdrawn from these vesicles under sterile conditions and cultured. The fluid from the majority of blebs was sterile; from a few the nonpathogenic saprophytic organisms of the skin were recovered, and in only one was a virulent organism, a streptococcus, cultured. In this case alone was the bleb grossly infected. In all the others, healing occurred promptly beneath the unruptured blebs and there was no evidence that the bleb fluid retarded healing.

Again, we were unorthodox and did not cleanse the wounds because we doubt that any cleansing other than vigorous scrubbing materially reduces the number of organisms on the wound. Such scrubbing of delicate, unprotected tissue would presumably result in more extensive injury and as much harm would be done as benefit derived.

A simple bland ointment was applied to the burn surface because, so far as has been determined, such an ointment does not injure the viable remnants of epithelium. Substances such as tannic acid or the triple dyes commonly recommended for the treatment of burns have recently been shown to retard the regeneration of epithelium.⁶ It is possible that plain petrolatum would be as good as or better than petrolatum with boric

*Masking of the patients was impossible because of the respiratory complications.

†The face and left hand of 1 patient were partially débrided and cleansed with soap and water before the general order was understood.

acid. Boric acid, however, may prevent the multiplication of pyocyanous organisms; pyocyanous was conspicuous by its absence in these patients. On the other hand, too rapid absorption of boric acid might result in poisoning. Boron was recovered in the urine of these patients, but no poisoning attributable to its presence was determined.

No substance has been proved to promote epithelial regeneration. It is believed by many that toxins are formed in burn wounds, but their presence has not been substantiated and surface agents designed to eliminate them are, therefore, of questionable value.

A sulfonamide was not incorporated in the ointment, not because we believe that it has an injurious effect on the epithelium but because absorption through the burn wound occurs and may be rapid and irregular and give rise to sulfonamide poisoning.^{7, 8} The sulfonamide administered internally permeates through the burn wound since it is freely diffusible out of the capillary wall. It is possible to control the level of sulfonamide in the body fluids by internal administration and thus prevent poisoning. At this hospital, sulfonamide levels have been demonstrated in bleb fluid equal to those in the blood plasma. Such observations were also made in the patients of the Coconut Grove fire. We are not certain, however, if sulfonamide therapy is withheld for more than forty-eight hours, that an adequate bacteriostatic level in the burn wound would be reached, since the cell spaces eventually become plugged with fibrin.

The original dressings were not changed on any of the patients until the fifth to tenth day, when a boric ointment dressing was reapplied. Full precautions were maintained in a temporary operating room set up on the isolation floor. Later, in preparation for grafting, saline or boric acid solution dressings were used to help liquefy the dry slough of the deep burns.

The main advantage of this surface treatment lies in its simplicity. In a civilian disaster, as in warfare, there is inevitably a disproportion between the number of casualties and the number of trained personnel. This was true in this disaster. The treatment was applied by relatively untrained workers, the skilled personnel of this hospital being free to care for the pressing problem of anoxia and shock. The activities required to apply the dressings were so unobtrusive that the administration of plasma and oxygen was not interfered with. The dressing relieved pain promptly, and all manipulations that tend to increase shock were cut to a minimum. Since the dressing does not interfere with the life-saving treatments and does not increase shock, it could be applied immediately

and therefore contamination and subsequent infection were reduced. It is so simple that hospital facilities, such as an operating room, are not required. The treatment is both first aid and definitive. Once applied, the dressings should not be touched for a week to ten days.

Because of its simplicity, this method of treatment has administrative advantages. It requires no complicated apparatus and nothing that is not used in other types of wounds. Special solutions, spray guns and heaters, all requiring extra space for storage or transportation, are not needed.

The results of this simplified treatment of the burned surface were gratifying. The second-degree or incomplete-thickness burns of the skin healed promptly without evidence of infection. The 17 patients having such burns had all been discharged by the end of two weeks. The only patients remaining in the hospital for a longer period were the 10 with deep or complete-thickness burns of the skin, the 1 with severe damage to the central nervous system from anoxia and the 4 held on account of residual signs of the pulmonary complications.

Early grafting of the deep burns was possible. The sloughing dead skin contained numerous organisms and there were occasional small abscesses beneath the necrotic tissue, but the wounds were remarkable because of the absence of invasive infection. The margins of the skin next to the granulating areas were not ulcerated or inflamed. There was no evidence of cellulitis, lymphangitis or lymphadenitis.

This absence of active infection is to be attributed to the chemotherapeutic program, not to any cleanliness of the burns on arrival. None of the burns were cultured before they were dressed originally because of the exigencies of the moment, so that the actual degree of contamination is not known. The first cultures were taken at the time of the first dressings. Cultures were also taken at subsequent dressings and the course of the bacterial flora was studied until healing occurred. The bleb fluid of unruptured blebs was cultured in many patients and found, as expected, to be sterile. Pathogenic staphylococci were found in almost all open wounds in the first and subsequent cultures, whereas streptococci were almost completely absent. In any similar group of burn patients the latter organism would have been present in the majority as a result of contamination from the respiratory tract. It is fair to believe that the sulfadiazine was responsible for the incongruity of incidence of these two types of bacteria.*

*Although penicillin was administered to 13 patients, it was given in what is now known to have been too small a dose, and it was not started until the sixth day. No decision can be reached regarding its effect for it is possible that the observed results are attributable to the sulfadiazine alone.

The burns of 9 of the patients were grafted. The extent of the surfaces grafted varied from 1 to 28 per cent of the body. The first graft was done on the twenty-third day, the last on the one hundred and twenty-fourth day. The initial graft on 2 patients did not survive, presumably because of the bacterial flora present in the granulations. The subsequent grafts on these patients took, as did all those on the other patients. The first of the grafted patients was discharged on the fortieth day, the next to the last on the one hundred and third day. All patients were discharged healed except for the last one, who was discharged on the one hundred and forty-third day. She was the most extensively burned patient to survive. On discharge there were still a few small granulating points in the grafted areas.

Many of the patients with deep burns of the hands have required physical therapy to restore function.

Clinical proof of the absence of invasive infection in the majority of the granulating areas of these patients is illustrated by the achievement in 1 patient. The skin on the dorsum of one hand was so severely burned that when the slough was cleared away the extensor tendons of two fingers lay exposed. A split graft to this area, had it been able to obtain an adequate blood supply, would have resulted in adherent tendons. Instead, the hand was implanted into the abdominal wall for two weeks. The graft of skin and subcutaneous fat took without incident and the tendons were saved. While the hand was in the abdominal wall there were minimal signs of inflammation. Had there been an active infection in the hand wound, the graft would not have taken and an abscess would have developed in the abdominal wall.

The absence of invasive infection not only permitted early successful grafting but also prevented any extension of the areas requiring grafting. Several deeply burned areas, at first considered to be complete-thickness burns, eventually epithelialized from numerous small islands of the rete. Had there been deep infection such islands would not have survived, and grafting would have been necessary.

Keloid overgrowth has formed in some of the deeply burned, ungrafted areas. It is too early to tell what will have to be done to them. Excision with grafting may be necessary, in which case it would have been wiser to have grafted the areas in the first place.

Pressure dressings have recently been advocated to reduce edema and promote healing. Although all the burns of the extremities, face and scalp were treated in this way, we do not think that we

can commit ourselves concerning its worth. On the extremities, the pressure undoubtedly did reduce the edema, the fluid being expressed upward above the dressings. On the face the fluid was expressed posteriorly to the scalp and then downward into the deep tissues of the neck and over the chest and shoulders. The dressings formed effective splints and, by decreasing the amount of lymph, may have reduced the spread of infection.

Ligation of veins for thrombophlebitis was required in 5 of the patients. The lesion was first suspected in 2 patients by the appearance in chest roentgenograms of areas suggesting pulmonary infarcts. In the other patients, local inflammation was the presenting sign. The cause of the phlebitis in one case was the use of an ankle vein for a constant intravenous injection; the superficial saphenous vein was ligated on the ninth day after the fire. In the other patients there was probably more than one cause, prolonged bed rest with immobility being the most important factor. In two cases, a pressure bandage applied to wounds of the thighs and not started at the ankle was probably a contributing factor. The thrombophlebitis bore no relation to the chemotherapy or the multiple femoral-vein punctures that a number of the patients required for blood studies, administration of plasma and whole-blood transfusions.

SOCIAL AND PSYCHIATRIC ASPECTS

A civilian disaster may induce social or psychiatric difficulties among either the survivors or the relatives of the dead. States of confusion, bewilderment and grief, requiring a psychiatrist's help, were encountered by the social-service workers among the relatives who came to the hospital seeking missing ones. Several of the injured had lost a husband, wife or close friends. One had lost a son and husband, and another, both her parents. Some of these patients made a good adjustment to their grief, others a poor one. All were aided by consultations with the psychiatrist. One patient who had lost his wife voluntarily returned to the hospital two weeks after his discharge for psychiatric care and eventually committed suicide. Although he had previously been an unstable person, his death is directly attributable to the disaster. The wisdom of the Social Service Department in its trained handling of relatives, and its prompt recognition of psychiatric disturbances, were noteworthy.

METABOLIC STUDIES

The numerous studies on blood, urine and feces that were made in order to guide the course of the therapy have yielded considerable information. No patient developed impairment of kidney

function, and this in spite of the fact that hemoglobinuria was present in 9 patients, being massive in 5. Albuminuria was encountered but left no residual.

Metabolic observations were also undertaken. A study of the nitrogen balance was made in 29 patients. In 23 of these the 17-ketosteroid excretion was followed throughout the hospital stay and, in some, longer. In 8 patients the potassium balance was studied. When an adequate nitrogen and caloric intake was possible, nitrogen balance was maintained. The excretion of nitrogen by the kidney was not influenced by the extent of the burn but was influenced by the sex of the patient. During the initial days when there was an inadequate caloric and nitrogen intake, the nitrogen balance was negative but there was not a comparable negative potassium balance. This indicates that the source of the nitrogen was not cellular protein.

The nitrogen deficit was less than anticipated in view of recent reports.⁹⁻¹¹ It is possible that this relatively low excretion of nitrogen may be attributed to the absence of infection in the burn wounds, since it is well known that infections are associated with a rapid excretion of nitrogen from the body.

The excretion of 17-ketosteroids in the urine rose above normal during the first five to seven days and then abruptly descended to a subnormal level; this level was maintained until convalescence was complete. The steroid excretion did not correlate with the changes observed in nitrogen balance. Such a relation has been reported elsewhere, and it is claimed that the adrenocortical hormone is responsible for the excretion of nitrogen by burned patients.¹¹

COMMENT

Many lessons can be learned from the experience with the victims of the Cocoanut Grove fire. Some were known before but their significance has been re-emphasized. The necessity for a prearranged plan of organization, administration and therapy for a large number of disaster victims is obvious.

Three important things in regard to burn therapy were learned. First, lung damage, presumably from both heat and irritating gases, may be an added complication and should be anticipated in any mode of therapy to be used on patients of a civilian fire. Unless one is aware of such a possibility, the meager initial signs in the lungs may be overlooked, and pulmonary edema and sudden death will result. The second thing learned, a corollary of the first, is that the adminis-

tration of morphine in large doses should not be given to burned patients when pulmonary complications exist. If mania is present, anoxia should be excluded as a cause before giving a respiratory depressant, although in burned patients covered with dirt and soot, anoxia may be hard to recognize. Thirdly, the treatment of the burned surface can be simplified, without compromising the care of the wound, by dispensing with débridement and cleansing, provided that adequate chemotherapy is administered. Also, a complicated surface agent is not necessary to obtain gratifying results.

DISCUSSION

DR. C. R. MULLINS, Concord: I should like to know a few more details of the chemotherapy. What blood levels did you maintain, how often did you have to give the sulfadiazine, and what were the doses?

DR. W. J. P. DYE, Wolfeboro: I should like to ask Dr. Cope a question concerning his method of administration of intravenous sulfadiazine. I had been under the impression that it should not be given at the time of or in conjunction with intravenous saline. Dr. Cope stated that this was administered through the tube in which saline and plasma were being administered.

DR. R. W. ROBINSON, Laconia: For the last two years, in the group where I am practicing, we have been using a 15 per cent phenol and vaseline ointment, without débridement, when dealing with burns, and I am confident that I have never seen any débridement of a surface burn that affords such complete relief or in which the burns heal so quickly and so readily with as little scarring. This was brought to our attention through a Dr. Miller, who has an extensive practice in a West Virginia hospital in the coal-mining district; he has been using this ointment for years. I was a bit hesitant at first because of the fear of phenol absorption and poison. Of course, as an antiseptic phenol is excellent. Furthermore, epithelialization of these wounds takes place underneath the ointment, seemingly at an accelerated rate.

In the beginning we used it in only a few cases, but we came to employ it more and more extensively. Our pathologist covered the wounds of laboratory animals with it, in an attempt to determine whether there was

any evidence of absorption of phenol. There was no such evidence whatsoever. In addition, patients who had been treated with this ointment and who had extensive burns, such as a whole leg or a leg and an arm or the abdomen, showed no evidence of phenol absorption, according to laboratory tests on the urine.

In other words, we have used no chemotherapy with this ointment, because we have had no infection whatsoever to the burned areas since using it.

DR A. L. MACMILLAN, JR., Concord. I should like to ask Dr. Cope to say a word or two about burns of the cornea.

DR COPE (closing). Perhaps I can answer the first two questions together, since they deal with chemotherapy.

All the patients had intravenous tubes in place, as I said. Each patient received 2 gm. of sodium sulfadiazine, injected intravenously by a technician. This was a simple procedure. Sodium sulfadiazine is a soluble salt, it is not like sulfadiazine alone. We have encountered no trouble from its use. It has been adopted as a routine procedure by the doctor who is in charge of surgical infections in our hospital.

The subsequent administration of sulfadiazine was by the continued intravenous route in those patients who could not swallow, and by mouth in those who could swallow. Each patient received an additional 6 gm. of sulfadiazine in the first twenty-four hours, and 4 gm. on the subsequent days, until it was omitted.

A few cases showed red cells in the urine. The blood levels, however, were carefully watched, and ranged between 4 and 10 mg. from the second day on. One patient reached 12 mg. on a single day. In the first twenty-four hours, the dose was not sufficient in 3 patients. Three patients developed sensitivity. One of them developed a drug fever and rash at the end of the second week, and the sulfadiazine was omitted.

Again, I want to emphasize that we consider this a successful therapeutic program. There are many things that enter into such a procedure against infection. First, the burn wound was covered early and protected immediately, thus reducing contamination. Secondly, the wound was not disturbed, reliance being placed on internal chemotherapy. Sulfadiazine was found each time that fluid from an exposed bleb was removed and analyzed and its concentration was equivalent to that in the blood

during the first ten days. However, if internal chemotherapy had been postponed until after forty-eight hours, I doubt that adequate levels in the bleb fluid would have been reached. By forty-eight hours, the intercellular spaces of the burned wound became blocked with fibrin, and passage of substances from the blood into the burned area and the bleb fluid was slowed.

DR DIE. What were the contraindications?

DR COPE. We did not believe that there were any.

As to Dr. Robinson's 15 per cent phenol in vaseline ointment, my objection to this is mainly that such a concentration of phenol undoubtedly damages otherwise viable epithelium, just as tannic acid does, or the triple dyes. A concentration of such a substance as phenol or the triple dyes that is sufficient to prevent bacterial growth is injurious to tissue. The sulfonamides and penicillin have the distinct advantage of being non-injurious to epithelium. They do not impede or retard epithelial regeneration in concentrations adequate for bacterial stasis. In that way, they are a godsend for the treatment of wounds.

As to the absorption of phenol, one might get a false picture by measuring or looking for it in the urine, because phenol is a protein precipitant and is rapidly fixed in the tissues. If any of it should get into the lymphatics, it would almost certainly be combined with protein; in this form, it might not be excreted by the kidneys promptly, yet could cause damage elsewhere. However, I should exclude phenol principally on the fact that it causes further injury. This is equally true for the triple dyes and tannic acid, if the concentration is high enough to keep down the infection. In deep burns that are incomplete when one puts on something that injures the epithelium, a full thickness burn is created and the injury is increased, even to the point of requiring grafting, which prolongs hospitalization. That is the reason why the use of such substances is in my opinion to be excluded.

About the burns of the cornea, there were 12 patients out of the 39 who had bilateral ulceration of the lower half of the cornea. At the Boston City Hospital, patients with burns of the eyes had the identical lesions. The treatment by our ophthalmologist was 5 per cent sulfadiazine ointment in petrolatum, put under the lid, the eyes were then closed, and a pressure dressing applied. The corneas in all the cases healed without scarring.

THE GASTROINTESTINAL SYMPTOMS OF HEART DISEASE*

LEWIS M. HURXTHAL, M.D.†

BOSTON

MANY persons with heart disease first consult a gastroenterologist because of symptoms of indigestion. On the other hand, an equal number consult a cardiologist because of symptoms that suggest heart disease but in reality arise from the gastrointestinal tract. Not infrequently the physician himself finds it difficult to decide on the source of the symptoms.

CONDITIONS ENCOUNTERED

Congenital Abnormalities

Gastrointestinal symptoms may arise from congenital abnormalities of the cardiovascular system. A right-sided aorta, a rare anomaly, causes difficulty in swallowing by pressure on the esophagus; it is easily demonstrated by fluoroscopy, although there is little reason to suspect it before this is done. Congenital heart disease in infants is not infrequently associated with malnutrition, because of frequent cough and vomiting, which often result in a difficult feeding problem. In later life the gastrointestinal symptoms of congenital heart disease are much the same as in other forms of heart disease when myocardial insufficiency has developed.

Aneurysm and Mitral Stenosis

Disease of the great vessels, particularly aneurysm, may rarely cause dysphagia. Rheumatic heart disease with mitral stenosis and auricular dilatation may at times produce considerable pressure and displacement of the esophagus, thereby causing noticeable difficulty in swallowing solid food.

Angina Pectoris

The pain of angina pectoris is characteristically substernal, as is the pain of coronary thrombosis; however, both show considerable variation in distribution. Radiation of pain into the jaw and teeth or into the throat is by no means rare. The spread of pain into the epigastrium, below the xiphoid, is comparatively rare but sometimes occurs in patients with a pendulous abdomen. Patients are apt to consider low substernal pain, however, as arising from the stomach. When the pain of coronary thrombosis is associated with gas, nausea or vomiting, or any combination of the three, as is frequently the case, suspicion is naturally directed to the gastrointestinal tract.

The diagnosis of angina pectoris depends entirely on a carefully taken and evaluated history. Generally speaking, the patient notices the following: The pain or discomfort is brought on by effort or emotion. Secondly, the pain may be less severe or absent if he walks when his stomach is empty or aggravated if he walks after eating a heavy meal. The patient thus relates the pain to his digestive tract. The pain may be less severe if the weather is warm or greater if it is cold. The pain may be further aggravated when walking if the patient is emotionally upset. The worst possible combination for the anginal patient, therefore, is cold weather, difficult footing, a full stomach and an upset mind. Thirdly, the patient even while walking often notes a relief of pain by the simple act of belching. This phenomenon is not easily explained, and it is even more difficult to make clear to the patient that his pain originates in the heart and not in the stomach.

Nocturnal pain and gastric distress due to coronary disease may result from overeating. However, it may be a serious sign, often heralding a major coronary infarction.

Nausea is a common accompaniment of coronary occlusion, but I have seen it only once as the major symptom of angina resulting from effort. It appeared and disappeared with substernal and epigastric distress and was readily quieted by nitroglycerin or cessation of effort.

Nausea and vomiting in an elderly patient may be the only sign of coronary thrombosis of the silent type. Much may depend on the patient's interpretation of his low sternal or epigastric discomfort and on whether he calls such discomfort pain. However, one can frequently obtain the usual history of distress by careful questioning. Care must be taken in evaluating nausea and vomiting when other gastrointestinal lesions are present, for example, carcinoma of the stomach, ulcer and gallstones. In these cases, electrocardiograms, especially serial ones, are of decided value. Differentiation of ruptured ulcer or other acute upper abdominal diseases, such as acute pancreatitis, gall-bladder colic or upper intestinal obstruction, is thus made possible. Difficulty arises, however, in cases in which electrocardiographic changes are absent, and a decision concerning exploration must be made. A careful appraisal of the patient's history is most helpful. In spite of all the evidence that can be collected, a decision

*Read at a meeting of the Dallas Southern Clinical Society, Dallas, Tex., March 23-26, 1942.

†Director, Department of Internal Medicine, Lahey Clinic; physician, New England Deaconess Hospital and New England Baptist Hospital, Boston.

may be impossible and surgery may be undertaken only to reveal a normal abdomen. Fortunately, these cases are infrequent.

Congestive Heart Failure

Acute cardiac decompensation with sudden distention of the liver may also lead one to suspect an acute upper abdominal emergency. However, other clinical signs pointing to a satisfactory diagnosis should be present. The presence of valvular disease, cardiac enlargement, dyspnea and even cyanosis should be striking enough so that an acutely engorged liver is not confused with other upper abdominal lesions.

With insidious congestive failure either from coronary disease or from hypertensive or valvular disease, the gastrointestinal symptoms are less acute and have no constant characteristics. Loss of appetite, gas and vague abdominal distress may result. In these cases, orthopnea may not be so marked, and liver enlargement may be of only moderate degree. Tenderness on palpation of the midepigastrium with resistance there and dullness over Traube's semilunar space should always make one suspect enlargement of the liver. When this is due to congestive failure, the neck veins are almost always engorged, particularly when the patient is in a recumbent position but also discernible when he is upright. This type of failure is often unrecognized in coronary disease. There may be an antecedent history of substernal pain. The physician should be alert to tachycardia and gallop rhythm or a ticktack quality of the heart sounds. A cough may lead one to suspect the heart; in fact, an acute bronchitis with severe coughing may precipitate heart failure. The cough then persists as a symptom of pulmonary congestion, and with digestive disturbances the true etiology of the symptoms remains obscure.

When congestive failure reaches the point where ascites is present, bowel function becomes poor, resulting in increasing gaseous distention, anorexia and indigestion.

This whole train of symptoms is also present in chronic passive congestion of the liver associated with ascites caused by chronic valvular disease or constricting pericarditis. Upper abdominal pain after eating may be so severe as to lead one to suspect gall-bladder disease. If congestion can be relieved, the pain may well disappear. In some cases of long standing, hepatic cirrhosis develops, often associated with some degree of jaundice. These patients are difficult to handle and may never be free of gastrointestinal symptoms. Boyer and White¹ have called attention to pain in the right upper quadrant on exertion associated with right-sided heart failure. In my experience, this

has not been encountered commonly, but like many symptoms often unnoticed it may occur more frequently than one suspects.

Embolism

Embolism is one of the most frequently undiagnosed causes of acute gastrointestinal symptoms, and may be pulmonary, renal, splenic, mesenteric or even cerebral. Perhaps the most frequent cause of embolism is rheumatic mitral stenosis, particularly when auricular fibrillation is present. Auricular fibrillation without valvular disease occasionally results in embolism. The mural thrombus of coronary infarction producing embolism may further complicate the gastrointestinal symptoms of this disease. Subacute bacterial endocarditis is another condition in which embolism may occur, as well as the whole train of digestive symptoms that accompany a severe infection. The pain may simulate gall-bladder or renal colic or appendicitis. The sudden onset of severe pain in a known cardiac patient is the keystone of diagnosis, and such a history should make the surgeon suspect the heart. A patient with mitral stenosis and auricular fibrillation should be warned that if such sudden attacks occur, he should immediately consult a physician and suggest the possible cause, thus averting serious and unnecessary operations. Should a diagnosis of mesenteric embolus be made, sufficient time (usually twenty-four to forty-eight hours) should elapse to permit demarcation to take place so that resection will be adequate.

Diaphragmatic Hernia

Certain gastrointestinal lesions frequently cause symptoms that simulate heart disease. Perhaps foremost among these lesions is diaphragmatic or hiatus hernia. This may produce substernal pain extending upward and may be associated with dyspnea, cyanosis and even shock, thus simulating acute coronary infarction. At times morphine must be given to relieve pain. The attacks may be frequent or infrequent. I remember a patient who was supposed to have had two coronary attacks, during which it was difficult or impossible to swallow food or liquid. This gave the clue. Although previous gastrointestinal studies had been done, the hernia was not found until the third examination.

Some of the most incredible complaints from an organic cause seem at first to have no such basis. All physicians tend to ridicule such complaints and classify the patient as being neurotic or as having hallucinations. However, one such case may make one more attentive to bizarre stories. A woman over fifty years of age complained of a loud swishing noise occurring occasionally

after meals and synchronous with her heart beat.² It could be heard ten or fifteen feet away. Examination and fluoroscopy of the heart and chest were negative. Not until some barium was swallowed was a large hiatus hernia discovered. When water and a liberal supply of soda were given, the heart beating against the entrapped portion of the stomach in the chest produced the churning motion of water and gas, thus causing the sound.

Anemia

Diaphragmatic hernia may cause symptoms of coronary disease in another way. Bleeding is not infrequent and marked anemia, with resultant anginal pain and considerable dyspnea on effort, may result. The bleeding may be difficult to control, but once the anemia is gone, the anginal symptoms usually disappear.

Cancer, particularly of the proximal colon, being often the unsuspected cause of anemia, may be another such instigator of cardiac symptoms. Indeed, anemia from any cause may play the same role. Severe congestive failure from anemia alone has been noted on several occasions.

Acute Dilatation of Stomach

Acute dilatation of the stomach after surgical operations may produce so much distress, along with tachycardia, dyspnea and even cyanosis, as to lead one to suspect some pulmonary or cardiac complication. Wise is the man who does not forget the usefulness of the stomach tube. The reverse may also be true,—that is, cardiac failure may cause dilatation of the stomach,—and although this is not common, the stomach tube should be used whenever it is suspected.

Disturbances of Rhythm

Functional cardiac mechanisms, such as paroxysmal auricular fibrillation, flutter and paroxysmal tachycardia, are frequently associated with indigestion. Premature beats, too, are at times a complaint. The latter are likely to be more noticeable during indigestion and are really unrelated to any gastrointestinal disturbance. Every physician has seen patients who had premature beats during examination but who were not conscious of them. Some patients think that paroxysmal auricular fibrillation is precipitated by gastrointestinal upsets, but when it comes to anything specific in the way of quantity or type of food, evidence is lacking. The only precipitating cause that I have encountered and that appears to have some relation is an alcoholic bout, particularly in persons who do not usually drink to excess. The withdrawal of tobacco, coffee and other suspected factors fails to prevent recurrence of these cardiac disturbances.

Many physicians apparently believe there is some relation between gall-bladder disease and functional heart disturbances or coronary disease. The relation between gall-bladder disease and functional heart disturbances is not impressive when viewed critically. However, gall-bladder disease and coronary disease are undoubtedly frequently associated, and the disturbance created by gallstones may aggravate the onset of anginal pain. Possibly the two diseases have a common cause, namely an abnormal deposition of cholesterol.

No precipitating causes of paroxysmal tachycardia have been discovered. In this disorder, as well as in paroxysmal auricular fibrillation or flutter, a sensation of fullness, gas or even nausea may occur during a prolonged attack. Early in life these attacks are well borne unless severe heart damage is present, but in the later years of life such tachycardias may, because of diminishing coronary circulation, produce substernal or high epigastric pain indistinguishable from anginal pain or that of coronary occlusion. Paroxysmal fibrillation is more likely to precipitate failure, not immediately but later, giving rise to the symptoms described under failure.

Symptoms from Treatment

Gastrointestinal symptoms due to treatment may be overlooked or unrecognized. The most important symptoms are those following the use of digitalis. Some patients cannot tolerate digitalis in doses below those that usually produce saturation, namely 1 to 2 gr., or 1 cat unit, per ten pounds of body weight. It is unwise to doubt the patient's statement that such is true. The claims made for various commercial preparations in this regard have little clinical proof. One should not inject intravenously or intramuscularly more than a quarter or a half of a theoretically digitalizing dose unless one is sure that no intolerance exists. Even if no intolerance exists, a calculated dose based on 1 cat unit per ten pounds of body weight should never be given intravenously in one injection but in divided doses not oftener than every three hours. The oral use of Urganin or the oral or the intravenous use of Cedalanid (lanatoside C) may in some cases be less liable to produce toxic symptoms.

Intolerance to such drugs as theobromine and ammonium chloride or even mercurials may prevent their use. Theophylline derivatives, especially theophylline sodium salicylate, seem to produce much less gastric irritation. Attention should be directed to the train of symptoms that may occur from too rapid or too great loss of fluid following diuretics. Two effects may result,

the first from concentration of digitalis bodies in the system, the second from excessive loss of sodium as the result of diuresis. Sudden and obscure deaths may have resulted from the above.

TREATMENT

In the treatment of these gastrointestinal symptoms, as well as of the heart itself, certain procedures should be avoided. Drastic purges are condemned, for although gas and distention may be relieved temporarily, they will recur. It is far better to avoid laxatives and saline cathartics and to rely on a low-roughage diet assisted by enemas of saline solution. A milk diet is suitable for some patients, but generally speaking it fails to keep the patient in a contented frame of mind. In my experience, a soft-solid diet with food that appeals has the advantage. In edema, the diet should have a low salt content, but not when it produces complete anorexia. The same is true for all drugs used. An attempt should be made to keep the patient happy, and to many patients this means a desire for and enjoyment of food. Thirst is often great. A daily fluid intake of 1500 cc. is handled well in most cases; less than this is rarely necessary and may result in an unhappy patient. Any gain in weight in a patient who has had congestive heart failure is almost certain to be caused by fluid, and it is never an encouraging sign.

The bedpan should not be used for cardiac patients, with the exception of those who are al-

most moribund, and then there is little need for it. The commode should be the receptacle of choice. The patient is moved so that his legs hang over the bed, he slides to his feet, pivots to the right or left as the case may be, and then sits down. This procedure can be carried out with a minimum of exertion.

SUMMARY

The gastrointestinal symptoms associated with heart disease are important for two reasons: first, they cause the patient to seek advice regarding his stomach, and secondly, they mislead even the physician. As a result, unnecessary roentgenologic studies may be carried out on a patient who can ill afford to go through such procedures because of his cardiac or financial status. The recognition of the heart condition as the principal cause may save patients from unnecessary and dangerous surgical procedures. Perhaps even more important is the recognition of gastrointestinal lesions causing symptoms of heart disease; to label a patient as having cardiac disease is inexcusable without substantial evidence in both the history and the physical findings. Other causes should be sought, and in such cases a thorough survey is indicated.

MEDICAL PROGRESS

ORTHOPEDIC SURGERY

WILLIAM A. ROGERS, M.D.*

BOSTON

THE problems peculiar to the surgery of trauma have become the focal point of interest of a considerable proportion of medical men, regardless of prewar surgical training. It seems appropriate, therefore, to devote this report of progress in orthopedic surgery to injury and, because of their importance, to the infections with which injury is associated.

TRAUMA AND INFECTION

Infection frequently follows injury and may become of far greater importance than the injury itself. The many and diverse advances made in the field of surgical infection during recent years are often confusing to the clinician and difficult of evaluation. The mechanism by which traumatic infection is produced and develops—in other words, the pattern of infection—varies considerably with the predominant infecting micro-organism. The infection pattern of each of the pathogenic bacteria responsible for these infections is as a rule clearly defined. By it the course of an infection by a given bacterium may be anticipated and appropriate safeguards taken to arrest the local sepsis, prevent complications, and control toxemia. Accurate identification of the infecting bacteria, both aerobic and anaerobic, by culture of the tissue excised at débridement and of the wound exudate is essential to optimum surgical management. Sulfonamide therapy is now recognized as a deterrent to the spread of sepsis, effective through controlling bacterial invasiveness. Antitoxin therapy aids in the control of serious toxemias by neutralizing bacterial toxins absorbed from the septic focus. Increasing attention is being paid to nutritional factors involved in the resistance to infection. Aided by immunotherapy and the bacteriostatic action of the sulfonamides, surgical treatment of the local sepsis is taking broader scope. Earlier drainage of pus is possible, as well as regional division of the septic focus. The immobilization of parts, long recognized as a means of placing wounds, as one

of the best preventives of infection. Reports concerning the results of penicillin and gramicidin are promising, and development of the former in some of the hospitals of the armed forces is being followed with close interest.

Path of Entrance of Bacteria

In general, any injury such as contusion, laceration, compound fracture or an incised or penetrating wound may provide a suitable milieu for bacteria. The local conditions that favor infection are devitalization or necrosis of tissue, diminished blood supply, increased tissue tension resulting from tissue breakdown, hemorrhagic accumulations and foreign bodies—bits of clothing, dirt, shell fragments and so forth. Entrance of bacteria into these areas may be gained through air-borne contamination or direct inoculation, by lymphatic extension from a remote focus, such as a minute crack between the toes in epidermophytosis, or by the hematogenous route. The bacteria introduced by direct inoculation are usually those present on the clothing and skin at the site of injury, although they may be present on the inflicting instrument. The bacteria that are associated with wound infection may, almost without exception, be cultivated from the skin or clothing at various times, the number and type varying with the region injured, with environmental factors and with previous exposure to contamination. Wounds involving the inner recesses of the body, such as the respiratory and gastrointestinal tracts, may, in addition, be inoculated directly with the organisms that make the walls of these systems their natural habitat. All the available evidence points strongly to the conclusion that open wounds are infected by streptococci and staphylococci by subsequent contamination much oftener than by direct inoculation at the time of infliction. Of 355 wounds sustained under various circumstances—that is, industrial, street and miscellaneous accidents—Hare and Willits¹ found no Group A hemolytic streptococci within two hours of infliction, but grew members of this group from 4 of 108 wounds during convalescence under active treatment. The only

which there were coagulase-positive staphylococci, 10 per cent showed a positive culture immediately following infliction, whereas 35 per cent did so during convalescence under treatment.

Contamination of wounds subsequent to infliction and during treatment is the most frequent source of wound infection. The practice of doing frequent dressings of open wounds on surgical wards is to be condemned. The air of these wards usually teems with pathogens introduced from wounds, dressings, bedclothing and the exhalations of other infected patients; from the dressing carriage and the breath and clothing of the attendants; and from the exhalations, skin and clothing of the patient. These organisms, often highly virulent, are blown about with the dust into every quarter of the ward by the constant coming and going of attendants, to settle in profusion upon the exposed wound surfaces. The results are often little short of disastrous. The clear recognition of this pernicious reinfection of wounds has led of late to the general adoption of closed-dressing methods, with incalculable saving in time, life, limb and function, and has eliminated a great deal of futile endeavor. It represents one of the major advances in the surgery of wounds. Open wound dressings should, therefore, be done not on the surgical ward but in a room set aside for the purpose. This room should be as free as possible of atmospheric commotion; adequate masks should be worn by everyone having anything to do with the wound, including the patient, and the dresser's hands should be prepared as for a clean surgical operation. Above these measures, the wound should be closed off from contamination at all other times. It should be exposed for dressing only when absolutely necessary,—for example, when there are signs of toxemia, increasing sepsis or complications, or saturation of the dressing,—and the dressing should then be done with the minimum of disturbance of the healing surfaces. The surgeon should plan at the time of operation to leave the wound in such a condition that only infrequent and nonmanipulative dressings will be necessary. Such a technic is now being stressed widely in civilian and military hospitals.

To the above there is a notable exception, namely, the Carrel-Dakin method of wound management. This superior technic is unfortunately fast becoming a lost art. Where complete facilities are available, and there is a surgical staff adequate in number and training, it undoubtedly has a definite place and will yield brilliant results.

Infecting Organisms

The bacteria commonly responsible for the infections that follow trauma are staphylococci (co-

agulase-positive), hemolytic streptococci, green-producing and nonhemolytic streptococci and clostridia. Anaerobic streptococci, enterococci and gram-negative bacilli (anaerobic) are less frequent wound pathogens. Statistical tables of wound contaminants naturally vary somewhat. In a bacterial analysis of a series of 200 fresh wounds that included lacerations, bullet wounds, dog and human bites, other puncture wounds, compound fractures, traumatic amputation and various automobile and other accidental wounds, Pulaski, Meleney and Spaeth² found the following distribution of organisms: *Staphylococcus aureus*, 52 per cent; hemolytic streptococci, 17 per cent; green-producing and nonhemolytic streptococci, 35 per cent; clostridia, 23 per cent; enterobacteria, 23 per cent; anaerobic nonhemolytic streptococci, 7 per cent; and anaerobic gram-negative bacilli, 2 per cent. The wounds contained on an average three different pathogenic species. This study also revealed that the older was the wound, the more anaerobes were present.

BACTERIOLOGY AND IMMUNOLOGY

A brief résumé of the more recent contributions to the bacteriology and immunology involved in the common types of traumatic infection seems appropriate.

Staphylococci

Identification. Staphylococci are classified at present according to their virulence for man. Strains of *Staph. aureus* are almost without exception pathogenic; those of *Staph. albus* may or may not be. The most reliable test of pathogenicity is the capacity of culture filtrates to coagulate citrated, oxalated or heparinized plasma. Such coagulation is due to a soluble enzymal by-product, staphylocoagulase, common to pathogenic strains (Chapman et al.^{3,4} and Fairbrother⁵), and is now employed in Army, Navy and most civilian hospitals.

Toxic factors. Staphylococcal pathogenicity depends rather more on the intense local necrotizing action of the bacteria themselves than on their capacity to produce toxins. However, there are several known potent toxins.

Staphylococcal toxin (potent culture filtrate) produces the following clearly demonstrable effects: skin necrosis when injected intradermally, a rapid intravenous lethal action in animals when given in huge doses and hemolysis in animals (probably of minor importance in man). Leukocidin, long associated with filtrate toxin through its destructive or inhibitory action on leukocytes, is still difficult of technical evaluation, although it is thought to be of considerable importance (Blair,⁶ Wright⁷ and Lyons⁸). Hyaluronidase, an enzyme,

the "spreading factor" of Duran-Reynals, has been extracted from cultures of virulent strains. It markedly increases tissue permeability to bacteria (and dyes), intensifies bacterial invasiveness, and enhances infection. It is soluble, stable and non-specific (Duran-Reynals^{9, 10} and McClean¹¹). A separate and distinct toxin, enterotoxin, is associated with staphylococci responsible for outbreaks of food poisoning. In animals its potency when administered intravenously is much greater than that when given orally. In man the symptoms produced are vomiting and diarrhea, abdominal cramping pains and headache. These were symptomatic features in the fatal Bundaberg cases, and Wright⁷ suggests this as the chief lethal factor in distinction to Blair's⁶ idea of the filtrate toxin as the predominant cause of death in this disaster. Lastly, Stevens¹² has reported 3 cases of scarlatiniform rash occurring in *Staph. aureus* infection, implying an uncommon staphylococcal erythrogenic toxin.

Source. Coagulase-staphylococci are normal inhabitants of the human skin and nasal passages. There is evidence that their prevalence on the skin is not so great as is generally believed. Gillespie, Devenish and Cowan¹³ found this group present on the skin of 19 per cent of 159 normal subjects, whereas Smith's¹⁴ finding was 5 per cent of 100 persons. The same investigators found the organisms in the nasal passages of these people in 3 and 32 per cent respectively.

Pattern of infection. From the clinical standpoint, by far the most striking feature commonly seen in staphylococcal infection is the intense local necrotizing action of the organisms. It is as though the tissues in the immediate vicinity had been scorched. Inflammatory fixation is usually prompt, violent and complete, resulting in the formation of simple abscess (less frequently in carbuncle). The lymph channels are blocked with fibrin thrombi, whereby entrance into the lymphatic system is denied to staphylococci or their toxic products. The capillaries thrombose, and the infected area is walled off from the rest of the body (Mentkin). All the evidence points to the assumption that staphylococci gain access to the thrombi formed in the vascular radicles, maintain themselves therein, and from these may enter the blood stream, in fragments detached from the infected thrombus. Expressed in clinical terms, microscopic septic thrombophlebitis may occur in the walls of the abscess. Lyons⁸ has emphasized this fundamental step, as well as the frequency of staphylococci as the responsible organism in the bacteremia that results from it. Conveyed in the blood stream within septic emboli, staphylococci may gain access to various tissues according to a definite pattern that

seems to be governed in part by infarction of the next capillary bed, in part by abscess of the infarcted area and in part by a thrombophlebitis that develops in the metastatic focus. Such metastatic lesions may in turn contribute to the blood stream further embolic contamination, whereby new foci develop. An intermittent bacteremia is thus set up. An abscess developing in an infarct infected with staphylococci may extend to the adjacent tissues or may rupture into a nearby serous cavity to produce a pleural or pericardial empyema.

The lesions that result from and contribute to staphylococcal bacteremia may include any of the following: pulmonary infarction, abscess, pneumonia, pleural empyema and pulmonary thrombophlebitis; visceral infarction and abscess; osteomyelitis; suppurative arthritis; thrombophlebitis of major veins; and brain abscess, thrombophlebitis and meningitis. To this list must be added staphylococcal endocarditis. The mechanism of valvular infection is as yet not defined. It is, however, well known that infected vegetations may become detached, contaminate the blood stream, and cause infarction and so forth. That these lesions comprise those found in metastatic staphylococcal infection is amply supported by autopsy findings. It is not the purpose of this review to discuss the clinical implication of each. The primary focus in these bacteremias may have healed and have been forgotten or may have escaped notice.

Such metastatic lesions vary in size from minute to massive, and may exhibit any part or all of the pattern. Thus, a pulmonary infarction may escape detection or may not occur, yet a positive blood culture attests to the passage of the bacteria through the lungs. On the other hand, infarction may be massive and promptly fatal, or the lesion may suppurate and become fatal later. Variations in local tissue resistance may explain many of these modifications in pattern. However, a suppurative focus in staphylococcal bacteremia is constant. When general infection becomes established, with numerous and extensive metastases and a constant embolic contamination of the blood stream, there is usually a fatal termination.

Exceptions to the above pattern must occur in the nature of things. These are noteworthy but do not alter the validity of the conception. Staphylococci may reverse the usual order and take on some of the attributes of streptococci to produce cellulitis, lymphangitis and a scarlatiniform rash.

Management. The advent of the sulfonamides has not lessened the importance of drainage of staphylococcal pus. The infected area should be exteriorized by adequate drainage, once the inflammation has become fixed locally. In severe infections every effort must be made to improve

the general condition of the patient by sedation and intravenous fluids, and by transfusion, if indicated, while the involved tissues are localizing the infection. Chemotherapy is begun at once. By this means bacterial invasiveness is held in check until natural resistance, aided by appropriate surgical measures, is adequate. Often valuable time may be gained by administering the sulfonamide (except sulfanilamide) intravenously in the form of the sodium salt (prepared capsules). It is essential that the infected part be immobilized by adequate splinting, as discussed later.

In spite of proper and adequate drainage, chemotherapy, splinting and ideal general care, metastatic infection through septic embolism may occur, and vigilance is required to detect intravascular infection at its inception. Such infection may be heralded by a chill, a temperature spike of 103°F. or over and a leukocytosis in excess of 15,000. A sustained high white-cell count, a continued fever, repeatedly positive blood cultures, a palpable thrombosed vein and a pulmonary infarct offer positive evidence of its persistence. Prompt measures directed to control this factor are indicated. Excision of the primary focus when feasible may be successful, or the implicated vein, if accessible, may be excised or ligated.

Once established, metastatic infection must be dealt with according to the same principles employed in the management of the primary focus. Evidence is beginning to appear that penicillin is a highly effective bacteriostatic and bactericidal agent in staphylococcal as well as many other infections. It is not yet available for civilian use.

Efforts to induce staphylococcal immunity in man by antitoxin, toxoid, antibacterial serum, bacteriophage or transfusion have not to date been successful in notably altering the course of infection. Lyons⁸ attributes the improvement claimed for these in reducing the mortality rate in staphylococcal bacteremias to an uncritical selection of cases or to a nonspecific shock reaction enhancing resistance. A true staphylococcal bacteriolysin—excepting possibly penicillin—has not yet been demonstrated.

Aerobic streptococci. The classification of streptococci by serologic methods has relieved much of the confusion that attended the general problem of streptococcal infection and complicated the many questions it raised. Thus the limitations of antibacterial serum therapy can be pointed out, sources of infection can be accurately traced, and the demonstration can be made that any of the various types of streptococci virulent for man may produce a given specific streptococcal clinical picture, such as scarlatina, erysipelas, septic sore throat and so forth. Lancefield, using extracts of

the coccal bodies, has divided the streptococci on the basis of precipitin reactions into thirteen groups—A through M. Each group differs serologically from the others on the basis of a group antigen, C substance, a carbohydrate. Each group is divisible into a number of types on the basis of its capsular material—M substance, a protein—and each includes hemolytic (β), green (α) and nonhemolytic (γ) dissociants. Griffith has derived a similar type classification by using a slide-agglutination technic. Group A (Lancefield) or *Streptococcus pyogenes* (Griffith) is responsible for 95 per cent of serious streptococcal human infections. Group A has been shown to contain at least twenty-nine types. Groups B, C, D, F, G and H may also cause human infection.

Toxic factors (Zinsser,¹⁵ Keefer¹⁶ and Wright⁷). Group A hemolytic streptococci may produce a number of toxic substances. Erythrogenic toxin (A and B), when occurring in large amounts in sensitive persons, gives rise to a scarlatinal rash, fever, vomiting and a rapid pulse. A hemolytic toxin, hemolysin (streptolysin), can be demonstrated, but the part played by this unstable toxin in streptococcal infection is not clear. A fibrinolysin appears to dissolve human fibrin and inhibits its formation from fibrinogen. Both the hemolysin and fibrinolysin are neutralized by streptococcal antitoxin. A leukocidin is also found in streptococcal filtrates that destroy leukocytes in vitro. It is antigenic and type specific. Hyaluronidase (Duran-Reynald's "spreading factor") is present in toxic filtrates.¹¹ It greatly increases tissue permeability and enhances the invasiveness and virulence of the organisms.

Source. Human, Group A, hemolytic streptococci are normal inhabitants of the lymphadenoid tissue of the throat. A considerable proportion of people are carriers of this group. The organism is found in the throat most commonly in winter and the early spring months, particularly in those who have been in contact with patients with acute streptococcal throat infection, especially if they have "colds." Such persons should scrupulously avoid operating rooms and attendance on wounds. It is generally known that Group A streptococci are rarely found on the skin.

Pattern of infection. Infection with hemolytic streptococci (Group A) manifests itself in a variety of ways. Two factors come into play in all these: toxic and septic.

The toxic manifestations are fever, rapid pulse, headache, malaise, prostration or shock, nausea or vomiting and often erythema.

The many clinical septic reactions reveal a considerable similarity. A rapidly spreading cellulitis

(phlegmon) is one of the outstanding characteristics, in sharp contrast with the rapid local fixation (simple abscess) accorded staphylococcal infection. This occurs as a widening area of induration, often erythematous. It marks the progress of the local infection, and is produced by edema, hyperemia, phagocytic cellular infiltration and vascular thrombi. Bacteria may be found throughout. The margins merge abruptly into the normal tissue without early barrier formation. Suppuration may occur and is found in a diffuse thin layer, or it may be more or less localized, as seen in staphylococcal infection. Fixation may not occur for forty-eight hours, during which time the infection may have spread, for example to involve almost the entire thigh or the full length of a limb.

An equally conspicuous characteristic of the streptococcal pattern is the selection by these organisms of certain tissues for their depredations. Such tissues include the following: the lymphatics (and vascular endothelium in general); the fasciae; the cavities with mesodermal epithelial lining, that is, tendon sheaths, joints, bursas and the peritoneum, pleura and pericardium; and the lungs.

The infection of lymphatics may be limited to the local reticular (capillary) portion of the lymphatic system around the wound, producing induration and, if the skin is involved, blushing or erythema. Extension from the lymphatic reticulum may occur into the adjacent tissues, producing cellulitis, with or without suppuration; infection of the reticular lymphatics of the skin in a highly virulent form constitutes erysipelas. Or the main lymph channels may become involved, either directly from a wound more or less appreciably infected or by extension from reticular infection. In the superficial pathways this involvement is revealed by the typical red streaking of lymphangitis; in the deep pathways, the indurated channel may be detected by palpation as a tender cord, especially if grease is applied to the skin to reduce friction (Lyons¹⁷). Extension into adjacent tissues may occur, producing cellulitis and suppuration, and if the intimate anatomic relation of veins and lymphatics is recalled, adjacent phlebitis and thrombophlebitis (Homans¹⁸) is not surprising. Lymph-node infection occurs, with or without appreciable lymph-channel involvement, but the portal of entry is usually readily demonstrable. Suppuration of the nodes may ensue; again, there may be extension into adjacent tissues in the form of cellulitis, with or without suppuration (Frank¹⁹).

Streptococcal infection in a fascial plane may sweep quickly along the deep fascia, usually parallel with the regional body surface, producing a typical cellulitis. Edema may be striking, and may clearly demarcate the limits of the infection. As

the sepsis progresses, erythematous areas may appear and suppuration may develop. The process may be somewhat limited by the fascial compartments. As in most streptococcal invasions, the condition is a grave one, and lymphatic, thrombophlebitic and metastatic complications may arise. The condition may be blood borne following contusion. Hemolytic streptococcal gangrene (Meleney²⁰), termed "gangrenous erysipelas" by the older writers, is essentially a virulent streptococcal cellulitis of the subcutaneous tissues with secondary skin involvement, and leads to massive gangrene. Toxic and septic complications add to the seriousness of the picture.

Infection of tendon sheaths, joints, bursas, pleura and so forth by hemolytic streptococci is frequent and may occur by direct inoculation, by extension from a neighboring focus or via the blood stream. Metastatic joint infection is not uncommon.

Bacteremia occurs when hemolytic streptococci reach the blood stream via the lymphatics, either directly or by extension through thrombophlebitic foci. Clearance is usually prompt unless bacteria continue to pour in. Cardiac valvular lesions may result and in turn provide further contamination from detached vegetations, as in staphylococcal bacteremia. Blood-borne streptococci are prone to metastasize to the lungs,—infarction and bronchopneumonia,—to the joints,—especially in children,—to bone in infants and to the subcutaneous tissues. Metastatic lesions follow the same general pattern of infection as do the primary lesions. They may in turn give rise to further metastases, and if these repeat the process, and infection becomes overwhelming, death finally ensues. A fatal termination may, however, occur with great rapidity in people of subnormal resistance attacked by great numbers of organisms of extremely high virulence.

Streptococci are destroyed in the body by phagocytosis and intracellular digestion, and in this, the macrophage and histiocyte are more effective than the polymorphonuclear leukocyte.

Management. The bacteriostatic action of the sulfonamides has proved to be of enormous value in these infections. By their use time is gained for the patient to marshal the natural forces of resistance and to fix the infection, and for the surgeon to institute most effectively the appropriate measures to improve the general condition and to combat the local sepsis. Complete bed rest in a hospital, sedation, maintenance of body fluids by intravenous saline solution and transfusion, if indicated, are standard general measures. For the local condition, rest by immobilization through appropriate splinting is of the first importance, as discussed below. Hot, moist dressings maintained

over the affected areas are of generally accepted value. Vigilant attention to the local sepsis and alertness to detect complications are essential. In the ordinary form of streptococcal cellulitis—and in erysipelas—surgical drainage should be deferred until suppuration occurs, and should then be restricted to the suppurative zone. In hemolytic streptococcus gangrene, on the contrary, longitudinal incisions are made through the involved tissue and are extended just beyond the margins into healthy tissue as soon as the diagnosis is established. Dakinization of the incisional wounds may then be employed to advantage.

The complications of hemolytic streptococcus sepsis are variously dealt with. Thrombophlebitic foci are blocked off by ligation or excision of the appropriate proximal vein, if it is accessible, and areas of suppuration are drained by incision confined within the suppurative zone. Joint infection is widely treated by repeated aspiration and immobilization; pulmonary, pleural and peritoneal infections are treated by appropriate special local measures.

Streptococcal antitoxin, although it neutralizes the erythrogenic toxin, has a limited therapeutic sphere in surgical infections. It may be helpful in cases in which the signs of intoxication are severe, but it does not alter the septic process. Scarlet fever convalescent serum gives fewer reactions of serum sickness, but it is less potent than the antitoxin. Recently, the purification of antitoxin has considerably lowered the incidence of serum reactions. At present the only method available for supplying specific antibacterial substances in hemolytic streptococcus infections is Lyons's¹⁷ immune-blood transfusion. It aids in clearing the blood stream of organisms and in localizing the infec-

tion, and is applicable to patients with bacteremia. A trained person is required to select the proper donor, that is, one compatible and possessed of sufficient type-specific opsonizing antibody. It has been demonstrated that, at the present time, all commercial antibacterial streptococcal serums are valueless, if not actually harmful.

(To be concluded)

MASSACHUSETTS' MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND SIXTY-SECOND ANNIVERSARY

May 24, 25 and 26, 1943

THE one hundred and sixty-second anniversary of the Massachusetts Medical Society was observed in Boston, on Monday, Tuesday and Wednesday, May 24, 25 and 26, 1943, at the Hotel Statler.

Twelve hundred and seventy-five physicians were registered.

MONDAY, MAY 24

The supervising censors met at 5:00 p.m. in the Hancock Room.

The Cotting Supper was served to 179 councilors in the Salle Moderne. The annual meeting of the Council was held in the Georgian Room at 7:00 p.m. There were 204 councilors in attendance.

TUESDAY, MAY 25

The first general session was opened by the president, Dr. George Leonard Schadt.

Dean Edwin J. Van Etten offered prayer.

Dr. Peirce H. Leavitt and Dr. Leroy E. Parkins acted as chairman and co-chairman respectively. The attendance was 500.

This session took the form of a symposium on burns with special reference to the Cocoanut Grove disaster.

The one hundred and sixty-second annual meeting of the Society was held at 11:00 a.m. in the Georgian Room. Dr. George Leonard Schadt presided. The attendance was 350.

Dr. Schadt spoke at length on the state of the Society. The Annual Oration, "Small Puddles," was delivered by Dr. Edward P. Bagg at the close of the meeting. During the course of the meeting the President introduced Dr. John F. Holmes, of Manchester, delegate from the New Hampshire Medical Society.

The annual luncheon was served in Parlors A, B and C to 151 fellows. Dr. Schadt presided, and Reverend Leo G. Burke, O.M.I., offered grace and benediction.

A clinical meeting was held in the Georgian Room from 2:00 to 5:00 p.m. under the chairmanship and co-chairmanship of Dr. Roger I. Lee and Dr. Dwight O'Hara respectively. The attendance was 550.

In the late afternoon, Mrs. George Leonard Schadt held a tea at the Harvard Club in honor of Mrs. Roger I. Lee and Mrs. Elmer S. Bagnall. Forty ladies were present.

The annual dinner was held in the Georgian Room at 7:00 p.m. with 325 in attendance. Rabbi Samuel J. Abrams said grace.

The speaker at the dinner was Mr. James A. Hamilton, of New Haven, president of the American Hospital Association, professor of hospital administration at Yale University and director of the New Haven Hospital.

Dr. George W. Thorn, Hersey Professor of the Theory and Practice of Physic, Harvard Medical School, and physician-in-chief, Peter Bent Brigham Hospital, delivered the Shattuck Lecture. His subject was "Physiologic Considerations in the Treatment of Nephritis."

WEDNESDAY, MAY 26

There was a general clinical meeting in the Georgian Room from 9:00 a.m. to 12:00 noon under the chairmanship and co-chairmanship of Dr. James W. Manary and Dr. Edward J. O'Brien, Jr., respectively. The attendance was 550.

From 12:00 noon until 2:00 p.m. there was a series of section meetings and luncheons.

The Section of Medicine held forth in Parlors B and C under the chairmanship of Dr. Laurence D. Chapin. The attendance was 44.

The Section of Surgery met in Parlor A, under the chairmanship of Dr. Oliver Cope. The attendance was 40.

The Section of Pediatrics met at the Junior League, Zero Marlboro Street, under the chairmanship of Dr. James M. Baty. The attendance was 33.

The Section of Obstetrics and Gynecology met at the Women's Educational and Industrial Union, 264 Boylston Street, under the chairmanship of Dr. Christopher J. Duncan. The attendance was 51.

The Section of Radiology met in Room 404, Hotel Statler, under the chairmanship of Dr. Joseph H. Marks. The attendance was 22.

The Section of Physiotherapy met in Parlors D and E, Hotel Statler, under the chairmanship of Dr. Henry A. Taddell. The attendance was 20.

The Section of Dermatology and Syphilology met in the Hancock Room, Hotel Statler, under the chairmanship of Dr. J. Harper Blaisdell. The attendance was 36.

From 2:00 to 5:00 p.m. a general clinical meeting was held in the Georgian Room under the chairmanship and co-chairmanship of Dr. Charles E. Mongan and Dr. Frank R. Ober, respectively. The attendance was 450.

There were 63 technical and 16 scientific exhibits.

The motion pictures attracted the attention of a large number of fellows.

The lists of admissions and deaths are appended, together with the official lists of officers, standing and special committees, councilors, censors and so forth.

MICHAEL A. TIGHE, *Secretary*

ANNUAL MEETING OF THE SOCIETY

The one hundred and sixty-second annual meeting of the Massachusetts Medical Society was called to order by the president, Dr. George Leonard Schadt, in the Georgian Room of the Hotel Statler in Boston at 11:00 a.m., May 25, 1943. There were approximately 350 fellows present.

The Secretary offered the record of the last annual meeting as published in the *New England Journal of Medicine*, issue of July 9, 1942, and moved its adoption. This motion was seconded by a fellow, and it was so ordered by vote of the Society.

Dr. Schadt presented Dr. John F. Holmes representative of the New Hampshire Medical Society. Dr. Holmes responded as follows:

I am very pleased to be here with you today, and I congratulate the Society on the wonderful program that has been presented this morning and the program that has been arranged for the rest of the meeting. It is a pleasure to be here, and I feel highly honored.

No delegates were listed from Maine, Vermont, Rhode Island or Connecticut. It was explained by the Secretary that these states were not represented owing to the exigencies of the War.

The Secretary announced that the membership of the Massachusetts Medical Society, as of May 26, 1942, was 5708, that the Society has gained during the current year 136 new members and 17 restorations, that it has lost 76 members by death, 16 by resignation and 16 by deprivation of their membership. He added that the net gain has been 45 and that the membership as of May 25, 1943, was 5753.

At the request of the President, the members stood for one minute in silent tribute to the memory of those fellows who had gone beyond.

At that point Dr. Peirce H. Leavitt, vice-president, assumed the chair. Dr. Schadt addressed the Society as follows:

Since our last meeting we have lost a valuable and honored servant of the Massachusetts Medical Society in the person of Dr. Charles Shorey Butler. Dr. Butler had been treasurer of the Massachusetts Medical Society, I believe, since 1931, approximately twelve years. He gave a great deal of himself to the Society, which he loved dearly. After many years of faithful service, he continued in office when the requirements of his health should have demanded a rest. He was finally prevailed on to ask for an indefinite leave of absence, which was granted. Dr. Butler died February 23, after an illness of several months. He had a peaceful death, and one that ended much suffering.

It was my privilege to know Dr. Butler intimately and to love him. He was a most kind and able man, one of the gentlemen of the old school, who, unfortunately, are passing from this scene.

At the request of Dr. Schadt the members stood for one minute in silent tribute to the memory of Dr. Butler.

It was moved and seconded that the President appoint a committee to bring in suitable resolutions on the death of Dr. Butler. It was so ordered by vote of the members.

The Secretary asked the district secretaries to aid his office in gathering the list of fellows who have entered and who will enter the service of our Country. Dr. Schadt seconded this request and called on the district presidents to help in this effort.

Dr. George L. Schadt delivered the presidential address on the state of the Society. He spoke as follows:

It is a pleasant duty for each president retiring from office to submit at the annual meeting a report on the state of the Society. This I shall do now.

I am very much pleased to be able to tell you that the state of the Massachusetts Medical Society at the present moment is excellent. This I hasten to assure you is not due to anything I have done, but due entirely to the unselfish work of the other officers, particularly Dr. Peirce H. Leavitt, vice president, Dr. Michael A. Tighe, secretary, and Dr. Eliot Hubbard, Jr., acting treasurer, and of course to the chairmen and the members of the various standing committees and the appointed committees during the year. I have learned anew—and it has been a very refreshing thought, too,—that when one wishes anything done one should ask a busy man. He will always have time to do it. I have asked many busy doctors during the year to accept appointments on committees as chairmen and as members, to carry out difficult and tedious assignments, and I am happy to say I did not have one refusal.

As has already been stated, the Massachusetts Medical Society is in excellent condition, both physically and

financially. Starting my year as your president, it was with the determination that we should have a peaceful, constructive year—a year free from petty and unprofitable squabbles. I think I am correct in saying that in the past we have had some petty squabbles and have always found them unprofitable. Your president has enjoyed the duties of his office very much. He has had the very happy privilege of making fifteen official visits to fourteen of the eighteen district medical societies. During these visits he has had the privilege and pleasure of meeting many of the members, and he hopes that he has made friends among them. It is a delightful experience to visit the different district societies, to talk with the officers and the members, and to learn the problems they have,—and it may be said these problems vary in the different sections of the State. Many of these problems, too, are local ones, and should be handled locally, and your president wishes to say that he has discovered that these problems are being handled in an excellent manner.

In going about among the various district societies, I have endeavored to tell the members what the Massachusetts Medical Society is doing, what some of the problems are that have arisen, to answer any questions the members may have, and also to gain the good will and support of the membership as a whole.

The late Dr. Burrage, our very efficient secretary for many years, wrote a most interesting and instructive history of the Massachusetts Medical Society, bringing it up, I believe, to 1926. Dr. Burrage left a number of volumes to the Society, requesting the secretary to present to each president during his term of office a copy of the book. Dr. Tighe presented me with my copy, and may I say I have read it from cover to cover and enjoyed it tremendously. I urge the members of the Society to read this history of the oldest medical society in the United States in point of uninterrupted meetings from the time of its beginning, in 1781, to the one hundred and sixty-second anniversary, in 1943. I cannot refrain in leaving this subject from expressing the hope that some historically minded member of the Society will carry on this history from the point where Dr. Burrage left off,—the year 1926,—bringing the history up to date.

May I now extend my heartfelt thanks and appreciation to all the officers with whom I have worked during the year and to all committee chairmen and committee members. I shall always have the deepest appreciation for what they accomplished for me during the year. It is not my purpose to mention many names in this report, but I do not believe the report would be complete without speaking of several.

The interest and the work of Dr. Michael A. Tighe, our secretary, is deserving of the gratitude of every member of the Society—a grand gentleman and a born secretary. Frankly, I find it difficult to understand how it would have been possible to have carried on without him. He knows every detail of what is going on in the Society, and his good advice and his assistance are always readily available. I wish at this time to extend to him my affectionate regard and my thanks for his help during this year.

May I also express to Dr. Eliot Hubbard, Jr., our acting treasurer, my deep appreciation for his help during this rather trying year. Dr. Hubbard stepped into the breach when our late treasurer, Dr. Charles S. Butler, found it impossible to continue with his duties, because of his health. Dr. Hubbard rather reluctantly assumed the office of acting treasurer. He gave unselfishly of his time

to the work, and on Dr. Butler's death took over all the duties of the office. Dr. Hubbard has steered the financial ship of state most capably, and though we shall all miss Dr. Butler, for whom I am sure we all had a great affection, we may feel that in Dr. Hubbard we have a worthy successor.

Dr. Charles Shorey Butler, the treasurer of the Massachusetts Medical Society since June 9, 1931, passed away on February 23, 1943. Dr. Butler served the Society as treasurer for approximately twelve years. His devotion to the Massachusetts Medical Society was complete. He gave unselfishly of his time and of himself in guarding its financial resources. He spent much time investigating investments that would make secure the principal. He was a lovable man—a man of whom it may well be said,—paraphrasing a remark by Oscar Wilde,—“... a charming gentleman, he had no enemies; he had many friends, and everyone loved him.” It was my privilege to know Dr. Butler intimately, and knowing him was to love him. He most reluctantly and only after much urging relinquished his duties, and then only when the state of his health made any other step impossible. In the death of Dr. Butler the Massachusetts Medical Society has lost a rare personality, an ideal treasurer and a friend.

The Society, as already stated, is in sound condition. It is strong, vigorous, virile. During the year it has conducted much constructive work, of which more will be said later. The Society has grown in membership, and as will be noted from the figures given herewith—we have increased in membership steadily in the last five years:

June 8, 1939	5438
May 22, 1940	5542
May 22, 1941	5639
May 26, 1942	5708
May 18, 1943	5752

These figures, of course, include members now in the armed services, but members nevertheless of the Massachusetts Medical Society. It seems to me the outstanding feature of these figures is the fact that during this tremendous cataclysmic war the Society has grown.

You will be interested, I am sure, to know—and I received these figures from Dr. Reginald Fitz, of Suffolk, at a recent meeting of the State Committee of the Procurement and Assignment Service—that according to the records of the *American Medical Directory* there were 8085 physicians in Massachusetts in 1942. Of this number 2734 were not members of the Society, and of this group 1269 are in the armed services. On the other hand, 5351 were members of the Massachusetts Medical Society. You will note an apparent discrepancy between these figures and the figures I have given you above, but since the directory is published only every other year there is, naturally, a lag in the figures. With reference to the number of members of the Society in the armed forces, I am informed that to date there is a total of 1256. Thus, a total of 2525 doctors from Massachusetts are members of the armed services—the Army, the Navy, the Marine Corps and the Public Health Service.

I am glad to say that the Council meetings held during the year have been well attended. There is one fly in the ointment, however: although many councilors attend the morning session, far too many leave at the intermission or directly after the Cotting Luncheon. As a matter of fact, there have been a number of occasions in past years and during this year that at the afternoon meeting

there has barely been a quorum, so that business might be transacted. As you and I know, the Council is the deliberative body of the Massachusetts Medical Society, its membership is based on the premise that every councilor represents twenty members of the district from which he comes. Therefore, when a councilor does not attend a Council meeting or attends only part of the meeting twenty members have no representation whatever or have only partial representation. In my opinion the districts should be most careful in the selection of their councilors electing those gentlemen who realize the importance of the position and will give up the three days necessary to come to Boston and to attend the Council meetings from beginning to end. It might just as well be said here that some of the councilors living in Boston and towns adjacent not only do not attend the Council meetings, but when they do attend leave at noon or shortly thereafter. This problem has been discussed at the Executive Committee meetings, and at the annual meeting of the Council it was moved and voted that the meetings in the future begin at 10 in the morning and continue without interruption to 2 in the afternoon, or until all business is transacted. I am sure that following this rule we shall have a quorum of the Council at every session.

The Committee on Membership has been most active and has done a splendid job. During 1942 and 1943 it received a total of 95 membership applications of which 65 were approved, 11 were disapproved, 9 were disapproved by the district committees, and 16 were held for further information. It is most interesting to note that there was close agreement between the central committee and the district committees in that there was only a difference of two in the number disapproved by these committees.

The Committee on Membership has recommended to the Executive Committee that the question of establishing a junior membership in the Massachusetts Medical Society be postponed for the time being. The question whether the Society should establish a junior membership was brought to the attention of Dr. Tighe, our secretary during the year. We discussed the question and then brought it to the attention of the Executive Committee which recommended that it be passed on to the Committee on Membership. It may be that at some time in the future junior memberships will develop into a worthwhile project in the Society.

The State Committee of the Procurement and Assignment Service has done an excellent piece of work under difficult and trying conditions. It was my privilege to sit in at most of the meetings, and I was also asked to go to Washington on a number of occasions to attend meetings presided over by Dr. Frank Lahey, chairman of the Directing Board of the Procurement and Assignment Service. These committee meetings were very much worth while. I am informed by Dr. Lahey, in a letter dated April 24, 1943, that approximately 2300 doctors from Massachusetts are in the armed forces, of whom 1200 are members of the Massachusetts Medical Society and 1100 are not. Again it should be mentioned that there is an apparent discrepancy between these figures and some figures given earlier in the report. The discrepancy is apparent only because the figures were arrived at on different dates and under different circumstances. The quota for Massachusetts in 1943—and I have seen these figures recently—is 33 per cent complete up to April 27. Five hundred and ninety more physicians will be needed from Massachusetts before the end of the year, and the majority of these physicians will have to be

taken from the large centers that is from the large districts—Suffolk, Middlesex, South, Norfolk, and other districts in and about Boston, Massachusetts, together with New York and Connecticut has the unenviable reputation of being one of the three states that have not filled their quotas for 1942, the percentage being 90 per cent. It is not necessary, I am sure, for me to tell you of the urgent need for physicians in the armed services. In going about the State and in visiting Washington, Chicago and other cities I have heard all the arguments pro and con. I have heard arguments about essentiality, until frankly I am fed up with the word. In my opinion, the word essential is the cause of more trouble in procuring the adequate number of physicians than any other one word or one thing, and I for one should like to see the whole question of essentiality ruled out. In my opinion it would be a very constructive thing and would help immeasurably in getting many physicians to enter the services who now are hesitating for one reason or another. If every doctor of service age, that is under forty-five or fifty, could be put in uniform on active service.

The Committee on Ethics and Discipline has had a busy year and under its very able chairman has done a fine piece of work. Your president has had the privilege of attending all its meetings. It is somewhat discouraging to listen to some of the problems that are brought up to this committee and to realize that there are men practicing our profession who apparently are not guided by the principle announced many years ago.

Do unto others as you would have them do unto you. Some of the cases presented have demonstrated a sordid viewpoint and greed, and others lack of appreciation of the ethics of medicine under which we practice in this enlightened age in the State of Massachusetts. May we hope that as the years go on there will be less and less of this in our profession, and less and less need for problems of this kind being brought before this committee.

In speaking of the Treasurer's report, may I again express to Dr. Hubbard our newly elected treasurer, my deep appreciation for his help during this trying year. Dr. Hubbard informs me that our finances are in excellent condition. We have, I believe approximately \$270,000 in bonds. Why the Society has this much money I do not know, and have never been able to find out to my satisfaction. It is my distinct impression that this money should be at work doing good deeds in the way of scholarships or in some other manner that the proper committee might well deem desirable. Dr. Hubbard further informs me that to date he has collected \$41,493 in dues but that there are still 706 members whose dues remain unpaid totaling \$7060. When this amount is received our treasurer will have collected \$48,553. I am quite sure that when the second bill goes out the members who have not paid will promptly do so. They will then receive the *New England Journal of Medicine* and will know that they are pulling their weight in the boat.

The *Journal* has continued its successful career under the able and brilliant editorship of a gentleman whose name you well know and under the direction of a very able committee. You will I am sure, be interested in the figures given herewith, showing the increase from year to year of subscriptions to the *Journal*, in 1943 totaling 10,347.

SUBSCRIBERS	1943	1942	1941	1940	1939
Al. N. S.	4 07	4 40	4573	4844	
Regist.	4494	3781	3668	2698	2305
Student	1551	696			
Totals	10347	8717	8041	7542	6355

This includes an order on May 1 for 541 subscriptions from the Surgeon General's Office, for distribution to all Army hospital installations of 25 beds or more.

During 1942, the *Journal* received 1984 new "outside" subscriptions, a total that is over 50 per cent greater than the total received in 1941. Of these subscriptions, 1085 were from regular subscribers and 899 from medical students. As would be expected there were many cancellations, undoubtedly owing to enlistment in the armed forces; the net increases were 216 regular subscribers and 711 medical students, which total 927. (As of December 31, 1942, journals were being sent to 5083 members of the Society (a decrease of 74 from the 1941 figure), 3462 regular subscribers and 1193 medical students, a total of 9738, which is greater by 853 than the total for 1941. This does not include 348 members of the New Hampshire Medical Society, who receive the *Journal* once a month.

The editorial board took action on 238 manuscripts during 1942, a decrease of 90 compared with the figure for 1941. Of these papers, 169, or 71 per cent, were accepted.

Operations for the year resulted in a net loss of \$17,550, which is approximately \$2450 less than the amount appropriated by the Society. The net amount received from the Society was \$19,100 the balance, approximately \$1550, being covered by an increase in current assets. The net cost per member of the Society was \$3.43, as compared with \$3.20 in 1941.

There was an increase in operating expenses due to the larger circulation, the increased cost of binding and mailing and the fact that in 1942 fifty-three issues of the *Journal* were distributed, which happens every seven years when January 1st falls on a Thursday.

It is difficult to predict what will happen in 1943. Undoubtedly the number of member subscribers will be decreased owing to their enlistment in the armed forces; on the other hand, it seems likely that the number of "outside" subscribers will hold its own or possibly show a slight increase in spite of cancellations. Expenses should decrease as a result of lower publication costs (provided the total circulation is smaller) and an increase in advertising revenue, owing to higher rates, which became effective on January 1. The decrease in the number of manuscripts submitted for publication may become a serious problem. In any event, the pagination of the *Journal* will be cut down since the members of the editorial board believe that the high standards for acceptance should not be lowered.

I am sure you will all agree with me that we may take deep satisfaction in having an exceptionally excellent journal, one that ranks very high throughout the Country.

As most of you already know, the Society has within recent years been carrying on under a budget system. The Committee on Finance, the chairman of which has given unselfishly of his time on this work, has prepared within recent years a very complete budget, and the Society has been living within this budget. Anyone who has had any experience at all in preparing budgets and living within them knows the difficulties that develop. However, I may say that we are living within our budget, and that notwithstanding a decrease in revenue due to members leaving for the armed services.

Within recent years there have developed within the Society several district-society journals. At present there

are three: one published by the Worcester District Medical Society; one published by the Norfolk District Medical Society; and one published by the Hampden District Medical Society. It is my studied opinion that the development of district medical society journals is a good thing for the Society, provided their activities are restricted to the district society that they represent. It is well, certainly, for the larger district societies that there be some medium through which the news of the district may be transmitted to its members from time to time: what the members are doing, what the hospitals in the district are doing or may have to offer in the way of clinics to the membership, and any other items that may be of local interest. I do not believe, however, that these journals should have a circulation larger than its membership. I am of the opinion that if and when the circulation of a district journal goes beyond that of its membership, then we may well look for and expect difficulties of one kind or another. Certainly these journals should not expect to compete with the *New England Journal of Medicine*, our own journal. Whereas the latter covers a much larger and a more comprehensive field, the former should, as already noted, devote their efforts to the county societies. I am rather hopeful that some of the larger district societies will see fit to publish journals, and it seems to me, too, that two, three or four adjacent smaller districts might well co-operate in publishing a journal that would cover their respective districts.

As I have gone about the State visiting the various district medical societies, I have taken the opportunity of pointing out the fact that the Massachusetts Medical Society as constituted today is practically completely decentralized, in that the Society is in the hands of its members, and not in the hands of any group in or about any of the districts or in or about Boston. Today we have three large state-wide committees. These committees have a duly elected member from each of the eighteen district societies. Besides this, the officers are all members *ex-officio*. These committees, as you know, are the Executive Committee of the Council, the Committee on Public Relations and the newly organized Committee on Legislation. The work of each is important, and having attended practically all the meetings of these three committees this year, I can assure you that much constructive work was done in behalf of the Society.

I should like to emphasize at this time a point I have made in talks to the various districts. It is this: any member of the Massachusetts Medical Society may at any time gain a hearing in the Council by bringing to the attention of one of the councilors from his district the subject he wishes discussed. His subject will be received and considered. If found worth while it will be accepted. In other words, I wish to re-emphasize the fact that the Massachusetts Medical Society today is a society of approximately 6000 doctors, and is, as Abraham Lincoln so well said: "A government of the people, for the people and by the people."

With reference to the Executive Committee of the Council, this committee has worked hard all year, and since the amount of work crossing Dr. Tighe's desk is increasing each year, the subjects and problems to be considered are many and diversified. This committee as originally planned and set up was organized to lessen the detail of work brought before the Council and to shorten the Council meetings. Unfortunately this desired re-

sult has not been achieved as yet, but we are quite sure that it will be in the years to come.

The Committee on Public Relations has held regular meetings and has discussed many very important problems—problems with which you are all familiar, I am sure. One of the most important of these, of course, was the work of a subcommittee meeting with Mrs Emma Tinsant, chairman of the Industrial Accident Board. As the result of these co-operative meetings, considerable constructive work has been achieved in bringing about a better approach to the care of the injured workman, and a more equitable treatment of the doctor on the individual case.

The Committee on Legislation is the last of these large committees organized—as a matter of fact, it was only organized this year, but has already done a splendid bit of work. I am happy to be able to report that without lessening the scope of its work, this committee was able to return to the treasurer \$1450 of its budget.

We are ending this year under a new set of by laws. The committee delegated to revise the by laws did an excellent piece of constructive work, and although we all did not see eye to eye with them, I am happy to say that the by laws have worked out well and with practically no confusion. One of the outstanding changes was that the collection of dues was placed in the office of the treasurer of the Society, instead of through the treasurers of the district societies. This collection of dues has worked out quite satisfactorily, and I am certain that in the years to come all the wrinkles will be smoothed out. It has, of course, meant a lot of work for the treasurer and his office, but he has done a splendid job and deserves much credit. As stated elsewhere in this report there are still 706 members who as yet have not paid their dues. I am quite sure, however, this has merely been an oversight and that soon all their dues will have been received.

We have had several new committees that have done excellent work. One of these is the Committee on Industrial Health. This committee, under the able chairmanship of one of our most distinguished members, has carried out an extremely constructive program. The committee has held two large meetings, both at the Harvard Club, one in November and the other the latter part of April. Both these meetings were well attended—the first having an attendance of around 300, and the latter 160. Both programs were excellent. One of the most gratifying features of these meetings was the caliber of the speakers and how very ready each of these distinguished gentlemen was to accept the committee's invitation to appear on the program and to bring to the members of the Society up-to-date viewpoints on the various problems of industrial health. This committee will, of course, continue its work, and I believe plans in the future to hold a meeting in Springfield, and probably in other cities in the Commonwealth.

As you know, because of war conditions, it was found necessary to postpone the New England Postgraduate Assembly for the duration. This is very much regretted but, of course, cannot be helped. Another necessity was the transference of the annual meeting this year from Springfield, where it was scheduled to be held, back to Boston. However, your officers and the Committee on Arrangements felt that under the circumstances, because of gasoline restrictions and the probability that we would be able to entertain a larger number of doctors in Boston than in Springfield, this was desirable.

Another new committee that has performed an outstanding service is the Military Postgraduate Committee, organized the latter part of last year. This committee developed as the result of the simultaneous appreciation on the part of three of our members of the need for the Society of developing some plan of service for the various Army camps and hospitals, as well as Navy hospitals. There seemed to be a definite necessity for assisting the personnel of the camps, hospitals and stations to obtain speakers and to develop worthwhile programs. The committee was organized in November, and since that time twenty-seven instructors have given thirty-two lectures at various Army installations and one at a Navy station. At a meeting of this committee the other evening, a gentleman representing the Navy voiced their appreciation of the advantages of this plan, and stated that they are going to adopt it and extend it throughout the Navy organization in the coming years.

This work has, of course, been carried on only by the Massachusetts Medical Society this year, but we believe that all the New England states should join in the program, since in practically all of them there are Army and Navy hospitals and stations that need assistance of this kind. Then too, the University of Vermont College of Medicine is situated in Burlington, the Yale University School of Medicine in New Haven, and I believe a two-year course is given by Dartmouth at Hanover. It should be a rather simple procedure to unite the New England states in this work. At the annual meeting of the Council last night, a motion was passed authorizing the Military Postgraduate Committee to continue its work and to get in touch with the other state societies through their secretaries, and our Society for the coming year was authorized to subsidize the expense of the program up to \$500.

Another new and important committee is the War Participation Committee, this committee having been organized within the last two weeks. Its personnel consists of a progressive group of our members, and the committee has an excellent chairman. I am sure it will do some grand work during the war and for some years after the war is over.

Among other new activities of the Society that have developed during the year I now mention the action of the Council at its meeting last evening in adopting a resolution authorizing the officers of the Society to take over more space in the Boston Medical Library. I for one firmly believe that our home is and should be in the Boston Medical Library, since in my opinion these two organizations should work shoulder to shoulder. Situated as it is in the Fenway and so centrally located, it is easy of access from any part of Boston. As I have stated, the Society will very shortly take over more space. In view of several progressive movements now on foot, there is no question that the Society will use the present space and added space much more in the future than it ever has in the past. Plans are in progress for developing a medical service bureau, similar to the bureau maintained at the New York Academy of Medicine. This bureau will and should be the center of medical information in the City of Boston, having on record every day what is going on in the various hospitals and what medical meetings are taking place—in other words, making available up-to-the-minute information to any member of the Society or to any doctor concerning what is going on in and about Boston that will interest him. You will have more information on this project from time to time.

Another important resolution that was offered, voted on and accepted was the plan to establish a Postwar Loan

Fund. This subject was submitted to the Council by your president as follows:

The subject I am going to discuss with you is something that has been in my mind all year long, but it seemed to me that I should wait until the annual meeting of the Council before bringing it out. I shall present the plan I have in mind and shall ask Dr. Roger I. Lee, the incoming president, to exercise his prerogatives in appointing a committee.

The last war, as you know, was a comparatively short war. Many of us had been in practice five, ten or fifteen years when we went away. I happened to be in service for twenty-two months; some of us were in for ten, twelve or fourteen months—I believe the average was fourteen months. We got back into practice quickly. Some of us were lucky and had little trouble, but a lot of the men had difficulty getting started. I know because I talked with a great many of them. They needed a car, or they needed an office.

I can think of the story of one man, let's call him Bill Smith, who came back and was quite a hero. He had been wounded severely and was brought home, and when he came back he met John Jones, a banker, who thought Bill Smith was a wonderful hero and told him what a fine fellow he was. And then he said to Bill Smith, "What can I do for you?" Bill replied, "I should like to see if I can borrow a little money." The banker said, "Of course you can. I'll be glad to give it to you. How much do you want?" "Twelve hundred dollars." "By the way, what about collateral?" John Jones asked. Bill Smith said, "This will be only for a year." However, the banker looked at him with a cold eye and said, "If you haven't any collateral I can't let you borrow the money." That was poor Bill Smith's position. He was a great hero, he had fought for his country in the war and he had been wounded, but he never got the \$1200—at least not from the banker.

A lot of men came back wounded and could not return to the type of practice they had engaged in before. They would have liked very much to have gone into something like refraction, but they did not have the money and they could not do it. As the result of the war many men lost out, not because of their service, but because of the fact they could not afford to rehabilitate themselves.

I think we have a great opportunity in the Massachusetts Medical Society today. This war is different. It is a long war. It has already lasted, so far as we are concerned, nearly a year and a half. It is going to last another two or three anyway. Our friends have gone, men who have been in practice five, ten or fifteen years. Many of those men are coming back wounded or in ill health. A surgeon may never be able to operate again. An internist may never be able to do that type of work. If he could do refraction or skin work, if he could get started with six or ten months' headway, it would be a great thing for him. A great many coming back are going to need special treatment until their wounds and their nerves are healed, and a majority of them are coming back without collateral.

My plan—and I have talked it over with a few men in the Society—is one to develop a fund in the Massachusetts Medical Society. Call it the Postwar

Loan Fund. Let it run something on the order of the Morris Plan, any member of the Society being able, without embarrassment and without collateral, to make application for a loan. That application is endorsed by one or two members of the Society. The amount would be limited, and each application would receive careful consideration. Such a scheme could be easily put into effect. To come to us rather than to an otherwise affable banker, or to a loan shark, would save our friends and our colleagues a tremendous amount of embarrassment.

I can visualize a man coming home and wanting to go to Harvard or Boston University or Tufts for postgraduate study. Incidentally, possibly the medical schools might be willing to cut the fee in half or cut it out entirely for the ex-service man. The amount to be borrowed might be \$1000 or \$1500. That can be decided. The time in which the loan has to be repaid might run one or two years. That, too, would be decided by a committee.

I can visualize further. I can see men who are not coming back, who are leaving wives, and children who need to be educated. There are quite a number of paths this plan might follow.

You say, "Well, where are you going to get the money?" I think the preliminary fund could be obtained by assessing every member of the Massachusetts Medical Society who had not had the privilege of serving with the armed forces, because of age, disability or another reason, \$10, with the opportunity of contributing more if he so desired. I think we could easily get \$50,000 to start with, and if we needed more we have a backlog of over \$200,000. Why does the Massachusetts Medical Society need \$200,000 in bonds? That is something which has been a source of worry to me all year long. We have done nothing with it. It has just been invested. There must be something constructive we can do with the money instead of having it lie in our treasury.

A resolution was made, seconded, and accepted that the incoming President appoint a committee known as the Postwar Loan Fund Committee. This committee's duties will be to study every phase of this problem, to submit a report of progress at the meetings of the Council in October and in February, and to submit a final report at the annual meeting of the Council in May, 1944. You will, of course, be kept informed through your councilors with reference to this subject, and at the annual meeting next year have the final report of the committee.

As previously stated, the work of many other committees, standing and special, has been excellent and deserves the deepest appreciation of every member of the Massachusetts Medical Society. The reports of these committees will be incorporated in the report of the annual meeting of the Council, held on Monday evening, May 24, so that I feel it is unnecessary to mention them at this time, with the exception that I wish again to express to the chairmen and to the members of every committee in the Society my profound feeling of obligation and deepest appreciation for what they have done for me and for the Society during this rather trying year.

I have purposely held to the end of this report certain remarks with reference to the Medical Service Corporation, better known to you as the Blue Shield. You are all familiar, I am sure, with the fact that the Blue Shield

was inaugurated by the Massachusetts Medical Society, and was developed through the very excellent work of Dr Thomas H Lanman and Dr James C McCann. Dr Lanman gave unselfishly of his time in obtaining from the Legislature the enabling act permitting us to organize this corporation. On his induction into the Army, it was necessary for him to relinquish the work, which was taken up by Dr McCann and carried on so efficiently. May I say at this point that it is impossible for me to adequately express my appreciation of the work of Dr Lanman, and my admiration for the work of Dr McCann in developing the Blue Shield and getting it where it is today. Dr McCann has given tirelessly of his time and his talents, and the Massachusetts Medical Society will ever be indebted to him. It was my pleasure and privilege to make many trips with Dr McCann to various parts of the country to study the different plans, and to determine the plan that would in the opinion of Dr McCann and his committee, work most efficiently in the Commonwealth of Massachusetts.

The Blue Shield began to function just about a year ago. The Blue Shield, gentlemen, in my opinion is a success, and as time goes on will be a greater success with each coming year. As a matter of fact I am convinced that the Blue Shield will be one of the most successful projects the Massachusetts Medical Society has ever initiated and carried through. It is quite true that it has been a bit slow in getting under way, but this has been due to many factors beyond the control of the Blue Shield. One of the important reasons was the entrance of this country into the war; another, the development of multiple taxes including the Victory tax. In my opinion by far the most important reason—and I say this with considerable diffidence and understanding—is that up to the present time the members of the Massachusetts Medical Society have on the whole not given the Blue Shield the united and loyal support that it should and must have. Unfortunately, many members have apparently made no effort to understand what the Blue Shield stands for and many of these gentlemen have criticized the Blue Shield and made statements they otherwise would not have made had they heard the clear exposition presented in practically every district medical society by Dr McCann and had they taken the time to read the several pamphlets sent to them and the articles appearing in the *New England Journal of Medicine*. It is my hope that in the ensuing year the members who have criticized and have not given their support to the Blue Shield will learn to understand it and will get back of it wholeheartedly. Only in this way will it be possible to make it the success that it should be.

At the present time there are forty groups enrolled in the Blue Shield, the total number of persons enrolled is 2329 with a total of 1170 contracts. Thirty-three hundred doctors have signed up as participating physicians but again may I say that unfortunately not all this number have taken the time or given the effort to understand what the Blue Shield is and what it will do for the individual and for them if given a fair trial. Frankly it was our hope at this time last year that we would have approximately 3000 persons enrolled in the Blue Shield. As stated we have 2329. With your support and cooperation we can, I believe, next year have 10,000 or more persons enrolled in the Blue Shield. May I earnestly beseech your understanding support of the Blue Shield. I am sure that if there is any question that is not clear

to any of you, merely writing to Dr McCann, or if you wish writing to me, will bring you a prompt answer and clarification of the problem.

In concluding this report on the state of the Society, may I express to the members of the Massachusetts Medical Society the realization on my part of the great honor it has done me in permitting me to serve as president of the Society for the last year. I can assure you that I have kept the interest of the Massachusetts Medical Society paramount at all times and that I have done my best to see that the Society was conducted in a dignified manner during the year.

And finally, I should like to leave with you a message that I have left with all the district societies that it has been my privilege to visit. It seems to me that a short quotation from a poem by Allan McIntosh, a young Scot who died in the last war, is most appropriate at this time—when all the world is in turmoil when we are all concerned about our loved ones and doing everything possible to bring about a quick victory and a lasting peace. Of the former, there is no question for in my opinion victory is only a matter of time and lasting peace a problem that we must and can solve. Allan McIntosh's lines appear on a very beautiful monument in Edinburgh—a memorial to the Scots who died in World War I. In his relief below the lines are shown Scottish pipers marching to war, their pipes playing, their scarfs blowing in the wind and back of them the soldiers and back of them the artisans followed by the wives, the sweethearts and the children. Above this bas-relief appear these inspiring lines—lines gentlemen that I beg you to make your own as they are and have been mine for many years:

If he life that waits I shall live forever
unconquered

If death I shall die at last strong in my
pride—and free

Dr Schadt was greeted with loud applause at the close of his masterly address, which showed a wide knowledge of the problems facing the Society.

Dr Schadt assumed the chair and introduced the annual orator, Dr Edward P. Bagg, of Holyoke, chief medical evacuation officer of Region II and president of the staff of the Holyoke Hospital. Dr Schadt called attention to the title of the oration—"Small Puddles." He wanted the members to understand that even though Dr Bagg was a pediatrician and therefore might be expected to know a good deal about small puddles the reference in the title had nothing to do with Dr Bagg's chosen field of endeavor.

The oration, which was published in the May 27 issue of the *New England Journal of Medicine* was beautifully and scholarly done and Dr Bagg was loudly applauded at its conclusion.

Dr Schadt introduced Dr Roger I. Lee, president for the ensuing year, Dr Elmer S. Bagnall, president-elect, Dr Eliot Hubbard, Jr., treasurer and Dr Michael A. Tighe, secretary. They all re-

sponded fittingly and expressed their pleasure at their enlarged opportunities to serve.

Dr. Frank R. Ober moved that the meeting adjourn. This motion was seconded by a member, and it was so voted.

Dr. Schadt declared the one hundred and sixty-second annual meeting of the Massachusetts Medical Society adjourned at 12:30 p.m.

MICHAEL A. TIGHE, *Secretary*

APPENDIX

ADMISSIONS RECORDED FROM MAY 26, 1942, TO MAY 25, 1943

YEAR OF ADMISSION	NAME AND RESIDENCE	MEDICAL SCHOOL
1942	*Abkowitz, Herbert, Everett	Kansas City University of Physicians and Surgeons
1942	*Adelman, Ernest Bernard, Bridgewater	Middlesex
1942	Albertowicz, Theodore John, Lowell	Tufts
1943	Allers, Olga Eleanore, Wellesley	Woman's Medical College of Pennsylvania
1942	Andreson, Lawrence Helmar, West Somerville	Tufts
1943	Angelo, Peter John, Quincy	Tufts
1942	Aranson, Albert, Newton Centre	Boston University
1942	*Argoff, Joseph, Fitchburg	Missouri College of Medicine and Science
1943	Avery, Bennett Franklin, Brookline	University of Michigan
1942	Baptista, Jesse, Fall River	Tufts
1943	*Berger, John Jacob, West Concord	Middlesex
1942	Berry, Franklyn Doane, New Bedford	Boston University
1942	*Bluestein, Jacob Kenneth, Bardsville	Middlesex
1942	*Boeh, Louis S., Conway	Middlesex
1943	Boyd, James Gelston, Westborough	Boston University
1942	Brady, Frank William, Lowell	Tufts
1942	*Brahm, Leo, Worcester	Friedrich Wilhelm University of Berlin
1942	*Buoniconto, Pasquale, Hathorne	Royal University of Naples
1942	Burger, Franklyn Donaldson, Wellesley Hills	University of Michigan
1943	*Burns, Francis Albert, Foxboro	Middlesex
1942	Chace, John Frederick, Hudson	Tufts
1942	Clauser, William Joseph, Boston	Indiana University
1942	Cole, William Gregory, Pittsfield	Columbia University
1942	†Cook, William Wilder, Quincy	Tufts
1942	*Cooperstein, Harry Joshua, Fall River	Middlesex
1942	*Corrado, John Charles, East Boston	Middlesex
1942	Cosgrove, James Francis, Jr., Worcester	Tufts
1942	*Cottone, Peter Paul, Marlboro	Middlesex
1942	Cox, Robert Downing, Worcester	Tufts
1942	Crowell, Lois Blanche, Tewksbury	Boston University
1943	Currier, Wilber Dale, Brookline	University of Nebraska
1942	Curry, John James, Boston	Tufts
1942	Desmet, George William, North Andover	Tufts
1942	*Devine, Joseph William, Boston	College of Physicians and Surgeons, Boston
1942	*Donovan, William Francis, Watertown	Middlesex
1942	*Eames, Thomas Harrison, Arlington	College of Physicians and Surgeons, Boston
1943	Elliot, Howard Lailey, Brookline	McGill
1943	Epstein, Ida Florence, Roxbury	New York Medical College and Flower Hospital
1942	*Erbe, Henry Herman, Otis	Middlesex
1942	Fadgen, John Francis, Clinton	Loyola University
1942	Fanger, Herbert, Salem	New York Medical College and Flower Hospital
1942	*Ferrante, Anthony, Allston	College of Physicians and Surgeons, Boston
1942	Forsley, Richard, Lowell	Tufts
1942	Frank, Howard Alvin, Boston	New York University
1943	Gettings, Thomas Lawrence, Fall River	Tufts
1942	*Giallombardo, Nicholas Perrone, Somerville	Middlesex
1942	Gidman, Francis Thomas, Boston	Tufts
1942	Glass, Sarah Elizabeth, Worcester	Rush Medical College
1942	*Goglia, Alfred Anthony, Taunton	College of Physicians and Surgeons, Boston

1943	*Goldman, Harold Sumner, Medford Middlesex
1942	*Goldstein, Morris, Cambridge	Middlesex
1942	Goodman, Doris Ryan, Natick	Tufts
1942	*Gordon, George Samuel, Lynn	...Middlesex
1943	*Gordon, Robert Knott, Winthrop	Middlesex
1942	Grandfield, Robert Edward, West Roxbury	Harvard
1942	Grandmont, Irene Olive, Foxboro	Boston University
1942	*Grzyb, Henry Andrew, Southbridge	College of Physicians and Surgeons, Boston
1942	Hardy, Erving Douglas, Worcester	Tufts
1942	Harken, Dwight Emory, Cambridge	Harvard
1942	Hayes, John Joseph, Jr, Brighton	Georgetown
1943	Hertig, Arthur Tremain, Newton Highlands	Harvard
1943	Hindle, William Vincent, Boston	Harvard
1943	*Hobica, Norman, Allston	Middlesex
1943	Howley, Edward Joseph, East Weymouth	Tufts
1943	Ingersoll, Francis McCall, Boston	Harvard
1942	Johnson, Carl Cordes, Brighton	Harvard
1942	*Johnson, Harry Taylor, Waltham	Middlesex
1943	Johnson, Walfred, Worcester	George Washington University
1942	*Kenney, John Aloysius, Mansfield	Midwest Medical School
1942	*Kenny, Donald Ellsworth, Medford	Middlesex
1942	Klam, Najeck, Boston	Boston University
1943	Klemperer, Friedrich Wilhelm, Lexington	Harvard
1943	Liebman, Sumner David, Boston	Harvard
1942	*Linauro, Ulysses David, Lynn	Middlesex
1942	Loofbourow, Dorothea Gano, Cambridge	University of Cincinnati
1942	*Lowenberg, Benjamin, Dorchester	University of Lausanne
1942	MacMahon, Harold Edward, Cambridge	University of Western Ontario
1943	Mankowich, Ralph, Waltham	Boston University
1943	*Manning Ralph A, Winchester	Middlesex
1943	McKell, David McCandless, Jr, Brookline	Harvard
1942	Miller, Edward Alexander, Sagamore	Boston University
1942	*Morrin, Harry Joseph, Roxbury	Middlesex
1942	*Nadelman, Benjamin Isidore, Roxbury	Middlesex
1942	Ober, Robert Emil, Cambridge	Tufts
1942	Olken, Harry George, Cambridge	Tufts
1942	Olshausen, Kenneth Wolfgang, Boston	University of California
1942	Porter, Reno Russell, Pepperell	Medical College of Virginia
1942	Potter, Theodore Alexander, West Newton	Boston University
1942	Quigley, George Edward, Newton	Boston University
1942	Rea, Stanley Leroy, Westfield	Stanford University
1943	Rice, Theodore Adams, Worcester	Harvard
1943	Richards, Anthony, Tewksbury	Tufts
1942	Rubin, Abraham Louis, Fort Devens	Tufts
1942	Rutledge, David Ivan, Wellesley Hills	University of Nebraska
1942	Ryan, William Francis, Palmer	Tufts
1942	*Sandler, Samuel, Cambridge	Middlesex
1942	Saward, Ernest Welton, Waltham	University of Rochester
1943	*Schiller, Louis, F	City University of Physicians and Surgeons
1942	†*Schott, Norbert A	of Physicians and Surgeons, Boston
1942	*Schwartz, Frank	of Physicians and Surgeons, Boston
1943	*Schwartz, Leo, Springfield	Middlesex
1943	Seligman, Arnold Max, Brookline	Harvard
1943	*Shalett, Irving Joseph, Brookline	Middlesex
1943	*Sherman, David Edward, Springfield	Middlesex
1942	Shipp, Luther Murry, Medford	Tufts
1943	Silveus, Esther, Boston	University of Pittsburgh
1942	Sise, Herbert Stanwood, Brookline	Harvard
1942	Skinner, David, Newton Centre	Harvard
1942	*Smith, Leonard, Westfield	Middlesex
1943	*Solomon, Alex, Adams	Middlesex
1942	Sostek, Samuel Bertram, Medford	Boston University
1943	*Souza, Charles Marshall, Dighton	Middlesex

ESSEX SOUTH — P. E. Tivnan, Salem.

COMMISSIONERS OF TRIAL FOR 1943-1944

BARNSTABLE — F. O. Cass, Provincetown.
BERKSHIRE — J. B. Thomes, Pittsfield.
BRISTOL NORTH — J. W. Cook, Mansfield.
BRISTOL SOUTH — A. C. Lewis, Fall River.
ESSEX NORTH — F. W. Anthony, Haverhill.
ESSEX SOUTH — O. C. Blair, Lynn.
FRANKLIN — K. W. D. Jacobus, Turners Falls.
HAMPDEN — J. M. Birnie, Springfield.
HAMPSHIRE — E. H. Copeland, Northampton.
MIDDLESEX EAST — W. H. Keleher, Woburn.
MIDDLESEX NORTH — J. F. Boyle, Lowell.
MIDDLESEX SOUTH — H. P. Stevens, Cambridge.
NORFOLK — W. J. Walton, Dorchester.
NORFOLK SOUTH — F. A. Bartlett, Wollaston.
PLYMOUTH — J. A. Carriuolo, Brockton.
SUFFOLK — J. R. Torbert, Boston.
WORCESTER — W. P. Bowers, Clinton.
WORCESTER NORTH — A. P. Lachance, Gardner.

OFFICERS OF THE SECTIONS FOR 1944

ELECTED BY THE SECTIONS

(The street addresses may be obtained from the
Directory of Officers and Fellows)

SECTION OF MEDICINE

Chairman, George D. Henderson, Holyoke; *secretary*,
Albert A. Hornor, Boston.

SECTION OF SURGERY

Chairman, Howard M. Clute, Boston; *secretary*,
Charles F. Twomey, East Lynn.

Executive Committee — Archibald M. Fraser, Boston
(1 year); Stanley J. G. Nowak, Belmont and Bos-
ton (2 years); Edward L. Young, Jr., Brookline
and Boston (3 years).

SECTION OF PEDIATRICS

Chairman, Leroy T. Stokes, Haverhill; *secretary*, Ger-
ald N. Hoefel, Cambridge.

Executive Committee — Harold L. Higgins, Newton,
chairman; Philip H. Sylvester, Boston, James Mar-
vin Baty, Belmont and Brookline.

SECTION OF OBSTETRICS AND GYNECOLOGY

Chairman, Christopher J. Duncan, Brookline; *vice-
chairman*, Arthur F. G. Edgelow, Springfield;
secretary, George Van S. Smith, Brookline.

SECTION OF RADIOLOGY

Chairman, Stanley A. Wilson, Salem; *secretary*,
George Levene, Chestnut Hill and Boston.

SECTION OF PHYSIOTHERAPY

Chairman, Wilmot L. Marden, Lynn; *secretary*, How-
ard Moore, Newton and Boston.

SECTION OF DERMATOLOGY AND SYPHILOLOGY

Chairman, John G. Downing, Newton and Boston;
secretary, G. Marshall Crawford, Lincoln and
Brookline.

OFFICERS OF THE DISTRICT MEDICAL SOCIETIES
FOR 1943-1944

ELECTED BY THE DISTRICT MEDICAL SOCIETIES AT THEIR
ANNUAL MEETINGS IN 1943

(The street addresses may be obtained from the
Directory of Officers and Fellows)

BARNSTABLE — *President*, Julius G. Kelley, Pocasset;
vice-president, Joseph N. Kelly, Orleans; *secretary*, Frank
Travers, Barnstable; *treasurer*, Harold F. Rowley, Har-
wich Port; *librarian*, Carroll H. Keene, Chatham.

BERKSHIRE — *President*, Charles T. Leslie, Pittsfield;
vice-president, Floyd R. Smith, Pittsfield; *secretary*,
N. Newall Copeland, Pittsfield; *treasurer*, Daniel N. Beers,
Pittsfield; *legislative and public-relations councilor*, Pat-
rick J. Sullivan, Dalton.

BRISTOL NORTH — *President*, Joseph L. Murphy, Taun-
ton; *vice-president*, William M. Stobbs, Attleboro; *sec-
retary*, William J. Morse, Jr., Attleboro; *treasurer*, Joseph
V. Chatigny, Taunton; *executive councilor*, William H.
Allen, Mansfield; *legislative councilor*, Joseph L. Murphy,
Taunton; *public-relations councilor*, James H. Brewster,
Attleboro.

BRISTOL SOUTH — *President*, Edward F. Shay, Fall
River; *vice-president*, Russell Wood, New Bedford; *sec-
retary and treasurer*, Albert H. Sterns, New Bedford;
public-relations councilor, Harold E. Perry, New Bedford

ESSEX NORTH — *President*, Robert C. Hannigen, Ames-
bury; *vice-president*, John T. Batal, Lawrence; *secretary*,
Harold R. Kurth, Lawrence; *treasurer*, Guy L. Richard-

son, Haverhill, *auditor*, Alphonse J Peter, Newburyport, *executive counselor*, Frank W Snow, Newburyport, *legislative counselor*, Edward H Ganley, Methuen, *public relations counselor*, Elmer S Bagnall, Groveland

ESSEX SOUTH—*President*, Paul E Tivnan, Salem, *vice president*, Edwin D Reynolds, Danvers, *secretary*, Henry D Stebbins, Marblehead, *treasurer*, Charles F Deering, Danvers, *executive and public relations counselor*, Loring Grimes, Swampscott, *legislative counselor*, Charles A Worthen, Lynn

FRANKLIN—*President*, Arthur W Hayes, Greenfield, *vice president*, Kenneth H Rice, South Deerfield, *secretary and treasurer*, Harry L Craft, Ashfield, *executive counselor*, Frederick J Barnard, Greenfield, *legislative counselor*, Howard M Kemp, Greenfield, *public relations counselor*, William J Pelletier, Turners Falls

HAMPDEN—*President*, Edward A Knowlton, Holyoke, *vice president*, Sidney R Cursley, Palmer, *secretary and treasurer*, Wayne C Barnes, Springfield, *executive counselor*, George L Steele, Springfield, *legislative counselor*, William A R Clappin, Springfield, *public relations counselor*, Patrick E Gear, Holyoke

HAMPSHIRE—*President*, Arthur N Ball, Northampton, *vice president*, Joseph D Fallon, Northampton, *secretary and treasurer*, Mary P Snook, Chesterfield, *librarian*, Abbie M O'Keefe, Northampton, *executive counselor*, L Beverly Pond, Easthampton, *legislative counselor*, Arthur N Ball, Northampton, *public relations counselor*, Alfred J Bonnevill, Hatfield

MIDDLESEX EAST—*President*, Roger M Burgoyne, Winchester, *vice president*, Joseph H Kerrigan, Stoneham, *secretary*, Roy W Layton, Melrose, *treasurer*, Albert E Small, Melrose, *librarian*, Raymond E Miltzer, Woburn, *executive counselor*, Edward M Halligan, Reading, *legislative counselor*, John M Wilcox, Woburn, *public relations counselor*, J Harper Rhudell, Winchester

MIDDLESEX NORTH—*President*, Herbert M Laffabee, Tewksbury, *vice president*, James J Cassidy, Lowell, *secretary*, Brendan D Leahy, Lowell, *treasurer*, Mason D Bryant, Lowell, *executive counselor*, William M Collins, Lowell, *legislative counselor*, Warren H Sherman, Lowell, *public relations counselor*, Daniel J Ellison, Lowell

MIDDLESEX SOUTH—*President*, Harold G Giddings, Newton Centre, *vice president*, Brainard F Conley, Malden, *secretary*, Alexander A Levi, Newton Centre,

treasurer, Fabryn Packard, Belmont, *orator*, George W Thorn, Cambridge, *executive counselor*, Dwight O Hara, Waltham, *legislative counselor*, Brainard F Conley, Malden, *public relations counselor*, John P Nelligan, Cambridge

NORFOLK—*President*, John C V Fisher, West Roxbury, *vice president*, Albert Ehrenfried, Brookline, *secretary*, Timothy F P Lyons, Milton, *treasurer*, Frederick Reis, Jamaica Plain, *executive counselor*, Carl Bearse, Boston, *legislative counselor*, John C V Fisher, West Roxbury, *public relations counselor*, Norman A Welch, West Roxbury

NORFOLK SOUTH—*President*, George V Higgins, Randolph, *vice president*, Henry A Robinson, Hingham, *secretary and librarian*, Eben K Jenkins, South Braintree, *treasurer*, Frank W Crawford, Holbrook, *executive counselor*, Daniel B Reardon, Quincy, *legislative counselor*, David L Belding, Hingham, *public relations counselor*, Fred A Bartlett, Wollaston

PLYMOUTH—*President*, Edward L Perry, Middleboro, *vice president*, Peerce H Leavitt, Brockton, *secretary*, Ralph C McLeod, Brockton, *treasurer*, Alton L Hurlburt, East Bridgewater, *librarian*, John H Weller, Bridgewater, *executive counselor*, Peerce H Leavitt, Brockton, *legislative counselor*, John J McNamara, Brockton, *public relations counselor*, Charles D McCann, Brockton

SUFFOLK—*President*, James P O'Hare, Boston, *vice president*, Howard M Clute, Boston, *secretary*, Robert L Goodale, Boston, *treasurer*, Richard S Eustis, Boston, *executive counselor*, Donald Munro, Boston, *legislative counselor*, William B Breed, Boston, *public relations counselor*, Albert A Hornor, Boston

WORCESTER—*President*, Andrew E O'Connell, Worcester, *vice president*, Benjamin H Alton, Worcester, *secretary*, Leslie P Leland, Worcester, *treasurer*, Edward P Disbrow, Worcester, *librarian*, John M Fallon, Worcester, *executive counselor*, Ralph S Perkins, Worcester, *legislative counselor*, Lester M Felton, Worcester, *public relations counselor*, John M Fallon, Worcester

WORCESTER NORTH—*President*, Herman D Bone, Gardner, *vice president*, Rudolf F Bachmann, Fitchburg, *secretary*, Edward A Adams, Fitchburg, *treasurer*, Frederick H Thompson, Jr, Fitchburg, *executive counselor*, C Bertram Gay, Fitchburg, *legislative counselor*, Francis A Reynolds, Athol, *public relations counselor*, James G Simmons, Fitchburg

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor**

BENJAMIN CASTLEMAN, M.D., *Acting Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 29291

PRESENTATION OF CASE

A fifty-three-year-old housewife entered the hospital because of fluid in the right chest.

Approximately three months prior to admission, following a cat scratch on the right thigh, she developed a tender red swelling of the thigh that spread in the next three days to the knee and upper calf. Simultaneously an "erysipeloid" reaction developed on the medial aspect of the left upper thigh. Her physician treated her with sulfadiazine by mouth for a week and the inflammation subsided. However, several days later the entire right leg became warm, swollen and mottled, and two or three days later the left leg assumed a similar appearance. After five weeks of bed rest most of the infection subsided. Three and a half weeks prior to admission, the patient became progressively short of breath, and ten days later at a community hospital 900 cc. of bloody fluid were withdrawn from the right pleural cavity. She felt better after the tap and returned home. Three days prior to admission marked breathlessness returned, and since the pleural fluid had reaccumulated, she was referred to this hospital for further care. During the illness her temperature usually ranged from 99.4 to 100°F., but on two occasions at night it rose to 103. There was no hemoptysis, chills, weight loss or night sweats.

The family and past histories were noncontributory.

Physical examination revealed a somewhat obese, slightly dyspneic woman who coughed occasionally but did not raise any sputum. The chest was large, and the anteroposterior diameter increased. There was limitation of expansion of the chest, particularly on the right. Flatness was percussed over the right chest posteriorly as high as the scapula. In this area the breath and voice sounds were inaudible. Anteriorly over the right apex and posteriorly over the left lower chest and just above the area of flatness on the right there were showers of fine crackling rales, principally on expiration, that did not clear after coughing.

*On leave of absence.

A blowing systolic murmur was heard over the entire precordium but best in the tricuspid area. There was moderate tenderness to deep palpation in both lower quadrants of the abdomen, and there was a sense of resistance in the lower mid-abdomen; no definite masses were felt. The right liver edge was percussed four fingerbreadths below the costal margin. Over both knees, the lateral aspect of the right ankle and the left calf there was a macular, bright-red, smooth rash. There was no edema. Homans's sign for thrombophlebitis was negative.

The blood pressure was 175 systolic, 95 diastolic. The temperature was 101.6°F., the pulse 112, and the respirations 31.

The red-cell count was 4,950,000, and a stained smear showed 64 per cent neutrophils. The urine was normal. A blood Hinton test was negative. The protein was 4.2 gm., the sugar 108 mg., and the nonprotein nitrogen 33 mg. per 100 cc.

An electrocardiogram showed normal sinus rhythm, with a rate of 115. The PR interval was 0.16 second. The T wave was low in Leads 1, 2, and 3, and inverted in Lead 4; there was slight right-axis deviation.

An x-ray film of the chest showed a moderate amount of fluid and air in the right pleural cavity that collapsed the right lung to about half its usual size. The fluid rose to the level of the third rib anteriorly. The right half of the diaphragm was elevated and showed considerable limitation in motion. There was some increase in the markings of the left lung field; otherwise this lung was not remarkable. The heart and mediastinum were slightly displaced to the left. The carina was not widened. The right main bronchus was not sufficiently well visualized to determine intrinsic disease. X-ray films and laminograms after removal of 1200 cc. of bloody xanthochromic fluid from the right chest revealed an apparent mass at the right hilus that extended into the right upper lobe.

During hospitalization the patient seemed quite short of breath but had few complaints. The temperature was usually 100°F.; the pulse ranged from 80 to 125, and the respirations from 20 to 45.

On the twelfth hospital day the patient suddenly began to sweat profusely and the pulse became rapid and thready. She denied pain. The cardiac apical rate was 120, and there was a prominent gallop rhythm. Respirations were 35, and the systolic blood pressure was 80. The extremities were cold and clammy. She was treated supportively and seemed somewhat better. Half an hour later the left arm became blue, painful and cold, and no brachial or radial pulse could be felt. She failed rapidly, became cyanotic and dyspneic, and died five minutes later.

DIFFERENTIAL DIAGNOSIS

DR CHESTER M. JONES: To me this history outlines a very curious sequence of events. It is obvious that the patient had some sort of infection in the lower extremities. She subsequently developed a bloody pleural effusion. At no time did she have pain in the chest, which is one of the striking things in the story. Three months after the onset of her first symptoms, she was admitted to the hospital, still with fluid in the chest, but at that time there was no swelling of the legs, although it had been present about two months previously. There still was, however, evidence of an inflammatory process described as an erythematous rash. The chest fluid was first bloody and later bloody and xanthochromic, indicating that blood had been there for a long time and that some of the hemoglobin had changed to bile pigment. I assume that the pneumothorax developed when air was introduced during the chest tap. Such a finding complicates the picture somewhat. Then with the terminal event, which came on suddenly, again there was no pain. If one states these facts in sequence—infection of the right thigh, something that was called erysipelas, subsequently warmth, swelling and mottling of the lower legs, first on the right and then on the left, and finally something in the chest—it is reasonable to say that this woman had infection, then thrombophlebitis in the deep veins of the legs, probably the superficial femoral vein, and finally pulmonary embolism.

There are several queer things, however, about this diagnosis. She never had any pain, either in the legs or in the chest. Furthermore, two months after the first swelling and redness appeared in the legs, we are told that she had no further swelling and the Homans's sign for phlebitis was negative. That does not prove there was not a deep phlebitis. Certainly we have seen numerous cases in which there was thrombophlebitis productive of a pulmonary embolus and in which we were unable to recognize the thrombophlebitis on the basis of physical signs in the leg. It is still more curious that when examined here there was no demonstrable edema, although more than once I have seen pulmonary embolism due to phlebitis of the deep veins of the leg that was not accompanied by demonstrable edema. It is not the thing to expect, however.

I should like to see the x-ray films of the chest at this time and raise the question whether the apparent mass described is suggestive of a primary bronchiogenic carcinoma. If so, we may be dealing with several diagnoses here instead of one. The collapse of the lung, apparently due to air and fluid in the pleural cavity, explains why the

diaphragm was high. After removal of a lot of fluid the lung was still collapsed, apparently because the diaphragm was very high.

DR LAURENCE L. ROBBINS: The diaphragm is high, but I doubt that it has anything to do with the air that is in the pleural cavity. Usually with collapse of the lung due to fluid and air in the pleural cavity the lung is compressed mechanically, and under these circumstances one would expect the right half of the diaphragm to be low.

DR JONES: Yes; but if there is compression against the collapse of the lung and compression of a bronchus that might cause a high diaphragm rather than a low one.

DR ROBBINS: Usually that happens when there is no fluid or air.

DR JONES: Do you think it is correct to say that the diaphragm is high?

DR ROBBINS: Yes.

DR JONES: The laminograms show something definite?

DR ROBBINS: Yes. Although they are not satisfactory in the usual sense, because we cannot see the outline of the right main bronchus or the trachea, they show a definite line in the area that should represent the base of the right upper lobe, with partial consolidation or something invading it. The shadow in the region of the hilus suggests enlarged lymph nodes. In this film it has a lobulated margin.

DR JONES: If there were a bronchiogenic carcinoma producing collapse of a portion of the lung, and a mass at the hilus, would you not expect a slightly different picture?

DR ROBBINS: Not necessarily. If this is a bronchiogenic carcinoma, I should say that it was located fairly close to the right upper lobe division, that is, in one of the secondary bronchi of the right upper lobe, and that the hilar mass was probably metastatic or direct extension of the tumor.

DR JONES: The thing that amazes me is the relatively painless and insidious occurrence of the bloody fluid in the pleural cavity. The absence of hemoptysis, pain and sudden onset in the early part of the story is I believe rather striking clinical evidence against pulmonary embolism. Furthermore, bloody fluid is quite unusual in the presence of pulmonary infarction unless the infarct is very large, or close to the pleural surface, in which case it is surprising there was no pain. I believe that a bloody pleural effusion can follow a peripheral infarction, but this sequence of events is rather unusual with the sort of story that this patient presented.

DR BENJAMIN CASTLEMAN: All bland infarcts extend to the pleural surface of the lung, and

only about 15 per cent of them are directly associated with pleural fluid, which may or may not be hemorrhagic.

DR. JONES: On the basis of the x-ray findings, it seems to me that this is not the picture one would expect with a pulmonary infarction or multiple pulmonary emboli. From the story I am more inclined to link the hilar lesion, which is definite in the x-ray film, with a malignant process, and I believe that bronchiogenic carcinoma is the most logical diagnosis. If that is so, it explains the bloody pleural fluid. I think it is fair to say that in addition to everything else, this patient had hypertensive heart disease and presumably was asthmatic. I think the cause of death may well have been an acute pulmonary embolus or coronary thrombosis. However, the rapidity with which the symptoms ensued makes me think that the terminal episode was associated with pulmonary embolism.

The electrocardiogram is going to be difficult to interpret. There was definite displacement of the heart when the electrocardiogram was taken. It had moved appreciably to the left, but the striking thing is, even with displacement of the heart to the left, that the electrocardiogram is recorded as showing right-axis deviation, when one would expect left-axis deviation. But in spite of the right-axis deviation, there was a low T wave in the first three leads and inversion of the T wave in Lead 4. That I believe is entirely consistent with right-sided heart failure and not at all inconsistent with pulmonary embolism. There was heart failure, as evidenced by the large liver, and it was undoubtedly right sided—let us say a cor pulmonale as a result of something going on in the chest. One of the conditions in which right-sided heart failure develops rather acutely is in association with pulmonary emboli.

I cannot make a diagnosis with any degree of assurance, but I believe that the patient had a thrombophlebitis of the lower extremities and I should not be at all surprised if there were pulmonary emboli. I also believe there was a terminal pulmonary embolism, together with right-sided heart failure. The systolic murmur over the tricuspid area is interesting; I think it was due to an incompetent or insufficient tricuspid valve and not necessarily to endocarditis. The mass in the mediastinum is probably better explained on the basis of malignancy than of anything else.

DR. JACOB LERMAN: How do you explain the final episode of arterial embolus to the left arm unless you assume endocarditis?

DR. JONES: That was a curious thing. It was noted distinctly as a terminal event, and I do not know how to interpret it. Half an hour after the

sudden collapse, the left arm was noted to be cold, blue and so forth. Of course one can say there was an embolic occlusion of the brachial artery associated with acute circulatory collapse. The systolic blood pressure dropped from 175 to 80.

A PHYSICIAN: How about something in the pulmonary veins? I know such lesions are rare.

DR. CASTLEMAN: Thrombi in the smaller pulmonary veins occur probably a lot more frequently than we realize.

A PHYSICIAN: I was thinking of embolus from the main pulmonary veins.

DR. CASTLEMAN: I have never seen one except as an extension from a mural thrombus in the left auricle or an extension from subacute bacterial endocarditis of the mitral valve.

DR. REED HARWOOD: I should like to mention the possibility of paradoxical embolism, part going through a septal defect to produce occlusion of the brachial artery.

CLINICAL DIAGNOSES

Carcinoma of lung.

Embolus of left brachial artery.

DR. JONES'S DIAGNOSES

Thrombophlebitis of legs.

Pulmonary embolism.

Acute cor pulmonale.

Bronchiogenic carcinoma?

Hypertensive heart disease.

ANATOMICAL DIAGNOSES

Adenocarcinoma of lung, right upper lobe, with metastases to bronchial, mesenteric and retroperitoneal lymph nodes, pulmonary lymphatics, liver, pleura and peritoneum.

Acute massive pulmonary embolism.

Phlebothrombosis of legs.

Subacute cor pulmonale.

Pulmonary infarct, left lower lobe.

Hemohydrothorax, right.

Hydrothorax, left.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: On opening the right pleural cavity a 1500 cc. of hemorrhagic, slightly turbid fluid was found, and scattered along the parietal pleura were numerous flecks of obvious carcinoma. The primary cancer was in the main bronchus of the right upper lobe, about 3 cm. from the carina. There were large metastatic bronchial lymph nodes, which represented the shadow seen in the right hilus. There were metastases throughout the liver, and this adequately explains the size of the liver. There were also metastases to the peritoneum and to some of the mesenteric and retroperitoneal lymph nodes. Microscopically the

tumor was a poorly differentiated adenocarcinoma. The left pleural cavity contained about 50 cc. of straw-colored fluid, and in the left lower lobe was a small hemorrhagic infarct of several days' duration. The immediate cause of death was a massive embolism to the main pulmonary artery, which apparently arose from thrombi in the deep veins of the calf of one leg. The veins of both legs were thrombosed. Most of the lymphatics throughout both lungs were plugged with carcinoma, and I believe this was the cause of the right-axis deviation. This is the second case of this condition, called "subacute cor pulmonale" by Brill and Robertson,¹ that we have recently seen.² I am sure that the infarct in the left lower lobe was not enough to have produced right-sided heart failure.

We examined the right subclavian and axillary veins and arteries but were unable to find an embolus.

CASE 29292

PRESENTATION OF CASE

A thirty-two-year-old unmarried woman, an office worker, entered the hospital complaining of nausea and soreness in the right abdomen.

Five months prior to admission, after a brisk walk, the patient noted the onset of crampy pain in the right lower quadrant, which doubled her up and caused nausea without vomiting. For two days following the attack she had tenderness in the right lower quadrant. Her physician found a soft movable mass under the umbilicus, and marked tenderness in the right lower quadrant. The uterus was small and anteverted. In the right vault was a tender, large, thick, cystic mass. Three days later the mass had disappeared, although there was still marked tenderness, as well as a hard tender mass, in the right lower quadrant. The patient was not seen for the next four months; during that period she had several similar attacks of crampy pain, which doubled her up and forced her to go to bed. During some attacks she felt nauseated and had either diarrhea or constipation. The last menstrual period began thirteen days prior to admission, and associated with this the patient had an attack of severe pain in the right lower quadrant and lower abdomen that lasted several hours. After a three-day menstrual flow the pain disappeared and she then resumed nor-

mal activity. During the past six months the patient had lost 10 pounds.

The family history was noncontributory. The menarche occurred at fourteen; periods were regular, with a twenty-eight-day interval, and lasted three days, four or five napkins being used a day. There was moderate crampy pain in the lower abdomen during the first day, but no clots were passed and there was no leukorrhea. Menstrual cramps had increased in severity during the two years prior to admission. Six years prior to admission, at a community hospital, a uterine suspension, appendectomy and resection of an ovarian cyst were performed.

Physical examination disclosed a well-developed and well-nourished woman. The heart and lungs were normal. There was a well-healed midline scar in the lower abdomen. Deep in the right lower quadrant there was a slightly tender, fairly indefinite sausage-shaped mass. Pelvic examination revealed a small uterus and cervix. The whole right vault was occupied by a large, tender, thick-walled mass.

The blood pressure was 110 systolic, 75 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a hemoglobin of 11.6 gm. per 100 cc. The urine was normal. A blood Hinton test was negative.

An operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FRANCIS INGERSOLL: It is of interest to note that this patient's pain was always on the right side, was always described as being crampy and was always associated with nausea without vomiting and that she had had increasing dysmenorrhea over a period of two years. The record does not state that the ovary was removed, so we can assume that she still had a portion of the right ovary. On physical examination there was a mass in the right lower quadrant and one in the pelvis. One cannot tell whether the same mass was felt by pelvic and abdominal examination.

This was an acute abdominal case, and it seems to me that the story of having had crampy abdominal pain with nausea makes one consider in the differential diagnosis some pathologic process that involved the gastrointestinal tract. On the other hand, since the pain seemed to come on with her periods, one must also consider a disease involving the genital tract. One might naturally assume that something was wrong with the appendix. However, since the appendix had been removed, it need not be considered in the differential diagnosis. Although it is often true that a patient is told

that the appendix has been removed when it has not, I think that we can discuss this case with the assumption that it was.

If one considers a pathologic process involving both the genital tract and the gastrointestinal tract, the first one that comes to mind is endometriosis. Cases have been reported in which the patient had endometriosis in the pelvis and endometriosis involving the bowel, usually around the sigmoid on the left side. Endometriosis may even involve the small bowel to such an extent that the patient has some degree of intestinal obstruction. So, as the first and best possibility to explain this patient's symptoms I should say that she had endometriosis, that the thick-walled cyst that was felt in the pelvis was an endometrioma, and that she also had an endometriosis that involved the small bowel. Possibly the small bowel was adherent to the endometrioma in the pelvis, and when she had her last episode of pain, which was with a period, she had bled into the endometrioma.

There are many other possibilities that should be considered. The patient might very well have had chronic pelvic inflammation. Certainly in pelvic inflammatory disease a person can have many gastrointestinal symptoms and often pain associated with periods. That might explain the symptoms, but it seems to me that with pelvic inflammatory disease the patient would not have been so comfortable, and she should have had more fever at some time during her illness. Although the episode five months prior to admission might have been the time that she had her first attack of pelvic infection, why a cystic mass was felt and later disappeared is hard to explain by pelvic inflammatory disease. This can, however, be explained by endometriosis. On the other hand, this might have been some type of bilateral ovarian cyst. Possibly the mass was an ovarian cyst that had twisted at the time of the first attack and had caused the pain after she had taken a walk. At the time she had the pelvic mass there was a mass in the right lower quadrant, so one would have to postulate that she had two ovarian cysts to account for the physical findings. One might explain the syndrome on the basis of regional enteritis, although that is just a stab in the dark. Certainly nausea and crampy pain can be caused by this disease, but one would expect some fever with it. An inflamed Meckel's diverticulum could produce a mass in the pelvis and something that could be felt in the right lower quadrant. However, the best explanation that I can offer is endometriosis, an endometrioma in the right vault to account for the gastrointestinal symptoms and endometriosis involving the small bowel.

DR. BENJAMIN CASTLEMAN: Have you anything to add, Dr. Meigs?

DR. JOE V. MEIGS: I think that Dr. Ingersoll has discussed the case exceedingly well, and I agree with him.

DR. CASTLEMAN: Perhaps you can answer the question about the umbilical mass, Dr. Simmons?

DR. FRED SIMMONS: The mass was described on the first office visit, and disappeared following a soapsuds enema three days later. I think that can rightly be termed a "red herring." I followed this woman for a month; she then disappeared and I had to write a letter to get her in again. The mass was still present, and since I could not rule out ovarian tumor, I believed that she needed exploration for that reason. Endometriosis was certainly a likely possibility.

On opening the abdomen we found an ovarian tumor on the right. The ovary was three times normal size, the upper third being replaced by a large cyst, which was believed to be endometriosis. The rest of the ovary was normal. Both tubes and ovaries were bound down by multiple, firm, dense adhesions, apparently the result of endometriosis. Adherent to the right tube and ovary was a greatly dilated ptotic type of cecum, which overlay the broad ligament and the back of the right cornu of the uterus. The rectum was adherent to the left tube and uterus. All the adhesions were broken up by sharp and blunt dissection, and the cecum was freed from the adnexa and uterus. I assumed that the first operation was for endometrioma in the right ovary and that many of the adhesions were due to the earlier operation. The patency of the right tube was demonstrated. Because the patient was thirty-two years old and because in this hospital the trend is toward conservative surgery in endometriosis for the sake of later childbearing, only the large cyst in the right ovary was resected, the uterus being suspended. She made an uneventful convalescence.

CLINICAL DIAGNOSES

Ovarian cyst.

Pelvic inflammatory disease.

DR. INGERSOLL'S DIAGNOSIS

Endometriosis of ovary, pelvis and small intestine.

ANATOMICAL DIAGNOSIS

Endometriosis of ovary and pelvis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The ovarian cyst showed characteristic endometriosis without evidence of inflammation around it.

DR MEIGS We see a lot of endometriosis at this hospital. Do you see it at the Free Hospital for Women, Dr Rock?

DR JOHN ROCK Yes, it is a common disease.

DR MEIGS It seems to me that endometriosis is a physiologic process and occurs in almost every woman who does not have children. Perhaps that is the answer, perhaps it is not. In a large percentage of the patients I operate on, if the pelvis is examined carefully an area of endometriosis will be found.¹ It is a disease, and it is pathologic when it is far enough advanced to interfere with normal function. When I find small areas of endometriosis I consider them to be of academic interest, and remove a piece for diagnosis. The percentage of endometriosis in my operative cases must be about 40 per cent. It is a condition that occurs in women who do not have children and is usually of little significance.

DR CASTLEMAN In what percentage would you say that it does not involve the ovary?

DR MEIGS A large percentage. It is frequently found in uterosacral ligaments and on the bladder flap near its junction with the uterus.

DR CASTLEMAN Do you believe that Sampson's² theory of the pathogenesis of endometriosis is ruled out by not finding it in the ovary?

DR MEIGS Sampson's work is so good that it is hard to deny it. I have a feeling that his explanation is correct for certain cases. We had a patient recently who had both tubes shut off by inflammatory disease for ten years, yet she had endometriosis in the uterosacral region.

A HOLMES CENTENNIAL

No prophet lacks honor, save in his own country. The centennial of Oliver Wendell Holmes's justly celebrated paper, "The Contagiousness of Puerperal Fever," published in the *New England Quarterly Journal of Medicine and Surgery* in April, 1843, was scarcely noted in Boston, though it received distinguished attention elsewhere. It was a noteworthy article, for it first introduced into America the doctrine of the infective nature of puerperal septicemia. Doctor Irving's address, published elsewhere in this issue of the *Journal*, makes honorable amends for the apparent neglect,

and pays deserved tribute to the man who dared raise his voice in the wilderness to point out the responsibility of physicians for the spread of child-bed fever.

The fame of Doctor Holmes, however, remains securely enshrined. His memory is freshly treasured in the Department of Anatomy at the Harvard Medical School, where he taught for so many years, and where many of his felicitous phrases are still repeated in lectures. As "Autocrat of the Breakfast Table" he diffused his genial humor and philosophy through the columns of the *Atlantic* to a much wider circle. Some of his poems, like "The Chambered Nautilus," are immortal. His character and personality are typical of the best in Boston, where for years he dwelt as *genius loci* of the Back Bay. Even a few are still alive who remember seeing him, in frock coat and silk hat, walking up Beacon Hill, and stopping to contemplate

The spendthrift crocus bursting through the mould
Naked and shivering with his cup of gold.

Anatomist, autocrat, poet, Oliver Wendell Holmes has left his soul on earth, and, like the *biformis vates* Horatius Flaccus, whom he so much resembled, he is double lived in Heaven too.

THE PLUMMER — VINSON SYNDROME

In 1922, Vinson,¹ of the Mayo Clinic, reported on his observations of 69 patients having inability to swallow as a prominent and sometimes only symptom. The paper was entitled "Hysterical Dysphagia." Fifty-seven of his patients were females, twelve were males. Patients with so-called "globus hystericus" were excluded from the series.

Vinson noted that the dysphagia usually began suddenly, often when the patient choked on a piece of solid food, the point of obstruction being high in the throat. This was followed by inability to swallow solid food, particularly meat and green vegetables, as well as difficulty in swallowing pills or capsules. Liquids and soft solids were usually well taken, and the loss of body weight was not marked. There did develop, however, a moderate

or secondary anemia, which Vinson thought was due to the quality of the food taken. In 37 of the patients the hemoglobin was 60 per cent or under. Enlargement of the spleen was noted in 12 cases in which the history of dysphagia was of long standing and the anemia, for the most part, was marked. Roentgenographic examinations in all cases gave negative results; and esophagoscopic examinations failed to reveal any lesions.

Although a plain esophageal sound was passed into the stomach in all cases, this resulted in no real stretching of the esophagus, and the effective treatment was on the basis of suggestion. This was followed by encouragement in eating solid foods and by the administration of iron and arsenic. Vinson states that the blood picture improved rapidly, the spleen returned to normal size and usually nothing further was needed to bring about an immediate, temporary cure. He found that recurrences were likely unless the patients were constantly reassured in regard to their condition. Sometimes a second passage of the sound was needed.

Vinson added that Plummer first pointed out this complex of dysphagia without organic obstruction, anemia and enlargement of the spleen. No reference, however, was given to Plummer's account, and it presumably was not published.

In the discussion of Vinson's paper, which was presented before the Minnesota State Medical Association on August 26, 1921, Dr R. Rizer, of Minneapolis, suggested that Vinson's name should be given to this disease. Another discussor did not agree with this point of view, but in spite of his opposition, the name "Plummer-Vinson Syndrome" came into the literature and has received wide recognition.

It is now known that this syndrome was described before 1922, when Vinson's paper was published. Hurst² has recently called attention to the fact that the syndrome was noted by Paterson³ at a meeting of the Laryngological Section of the Royal Society of Medicine, held on May 2, 1919. Paterson gave an even more complete description of the condition than did Vinson, for he noted

atrophy of the mucous membrane of the tongue, which is now known to accompany this condition. At the same meeting, this syndrome was also described by Kelly.⁴ He, too, noticed that in a few cases the mucous membrane of the pharynx had a pale, waxy aspect and that the tongue was smooth and devoid of papillae. Kelly attributed this appearance to the anemia resulting from the restricted and often insufficient diet. Hurst does not refer to this paper by Kelly, which seems to have equal value with that by Paterson. It is Hurst's opinion that the condition should be known as "the upper dysphagia with anemia syndrome of Paterson." To this should be added the name of Kelly. It would be even more advisable to use the term suggested by Suzman,⁵ 'the syndrome of anemia, glossitis and dysphagia'.

Hurst states that the syndrome occurs in about 15 per cent of all cases of simple achlorhydric anemia, is usually noted between the ages of thirty and fifty and is rarely found in men. It appears to be the direct result of iron deficiency due to a diet containing too little meat and green vegetables. The anemia is rapidly overcome by the administration of 30 gr. of iron and ammonium citrate three times a day. In some long standing cases, malignant degeneration has followed the atrophy of the mucous membrane.

A good many facts about this syndrome are not clear, and differentiation from allied conditions is not always possible. Strictly speaking, the dysphagia is due to a functional loss in the first stage of swallowing, in moving the food from the anterior part of the mouth back to the pharyngeal wall, where the reflex is initiated. The swallowing itself, when the bolus reaches this point, is normal, and thus the condition is not demonstrable by fluoroscopy with barium. The syndrome should therefore not be confused with many conditions that result in difficulty in swallowing in the second stage, such as constriction of the pharynx and esophagus due to scars or tumor and paralysis of the pharyngeal muscles occurring temporarily in myasthenia gravis and permanently in bulbar paralysis. There may, however, be anemic condi-

THE PLUMMER—VINSON SYNDROME

In 1922, Vinson,¹ of the Mayo Clinic, reported on his observations of 69 patients having inability to swallow as a prominent and sometimes only symptom. The paper was entitled "Hysterical Dysphagia." Fifty-seven of his patients were females, twelve were males. Patients with so-called "globus hystericus" were excluded from the series.

Vinson noted that the dysphagia usually began suddenly, often when the patient choked on a piece of solid food, the point of obstruction being high in the throat. This was followed by inability to swallow solid food, particularly meat and green vegetables, as well as difficulty in swallowing pills or capsules. Liquids and soft solids were usually well taken, and the loss of body weight was not marked. There did develop, however, a moderate

than is necessary in the care of military casualties, for the following reasons:

The injured may include individuals of all ages and with various types of pre-existing disease, instead of a selected group of healthy young males. The possibility of toxic effects is therefore greatly enhanced. Moreover, it is assumed that in civilian injuries, hospitalization will be possible in a relatively short time, whereas in military operations such is not always the case. This usually makes it possible to postpone all consideration of chemotherapy until the injured have been hospitalized. It is then possible to administer sulfonamides with better safeguards and to consider such contraindications as other pathological conditions or known sensitivity to individual drugs. The dangers of dehydration can also be better prevented or overcome under such circumstances.

In a discussion of intra-abdominal wounds leading to perforation of the hollow viscera, the revised pamphlet advises sodium sulfadiazine as the drug of choice for parenteral administration, which is considered preferable to oral therapy during the first forty-eight hours. Sulfanilamide was recommended in the previous edition. Concentrated solutions of sodium sulfadiazine are not recommended for subcutaneous or intramuscular routes, but it is pointed out that weak (0.5 per cent) solutions may be used with little danger of sloughing of the tissues.

Special emphasis is placed on the danger of giving sulfonamide drugs to a patient who is not voiding normally (over 1000 cc per day). The pamphlet warns:

Should circumstances require sulfonamide administration in the presence of inadequate urinary output the urine should be watched for evidence of renal damage and the dosage of drug adjusted so that a blood concentration, as evidenced by daily determinations, not to exceed 10 mg per 100 cc, is maintained. If further diminution of the urinary output occurs administration of the drug should be stopped immediately and fluids should be forced orally, if possible, and by means of glucose and water (5 per cent in sterile distilled water) intravenously if necessary. If anuria due to bilateral obstruction of the ureters develops, ureteral catheterization and lavage of the renal pelvis may be required.

The emergency care of burns is outlined as follows:

Whenever casualties with extensive burns can be admitted to hospitals without delay, and definitive treatment can be instituted promptly, morphine sulfate, $\frac{1}{2}$ gr., should be administered at the scene of the incident and no local therapy applied to the burned area except sterile gauze to exposed surfaces to prevent infection.

The most notable change in the OCD pamphlet is the withdrawal of the recommendation of the use of ointments or jellies containing tannic acid in the first aid treatment of burns. The new advice given is that when definitive care cannot be carried out within two hours, the patient should receive sufficient morphine to relieve pain (not less than $\frac{1}{2}$ gr., except in patients with lung and bronchial [and cerebral] damage, the very old or the very young) and the burned surfaces should be covered with sterile boric acid ointment or petrolatum over

which one or two layers of gauze of fine mesh (44) is smoothly applied. Over this dressing thick sterile gauze or sterile cotton waste is placed and the entire dressing is bandaged firmly but not tightly. Substitution of jelly containing 5 per cent sulfathiazole in water soluble base, which is supplied by the OCD Carrying Case A for mobile medical teams, is permissible.

The discussion of definitive treatment of burns has been expanded to stress the necessity for administration of large amounts of plasma.

In patients with severe burns, quantities up to 12 units or more may be required in the first twenty-four hours. To the patient in critical condition, plasma must be given rapidly (as much as 500 cc in ten minutes may be necessary) and not allowed to flow drop by drop. It must never be administered by any other than the intravenous route. Syringe injection may be used. If facilities for hematocrit determinations are available, the following general rule can be used for guidance regarding the amount of plasma required. For each point that the hematocrit is above 50 per cent cells at least 100 cc of plasma should be administered. If clinically satisfactory results are not obtained with this dosage, larger quantities should be given.

A footnote points out that rapid administration of intravenous fluids may be dangerous to cardiac patients and that the physician's judgment will have to determine the amount as well as the rate of administration in such cases.

The pamphlet describes open and closed treatment for burns. The open treatment that is now considered the treatment of choice and is especially recommended for the treatment of burns of the hands, face, feet, perineum and genitalia, consists essentially of the application of boric acid ointment or petrolatum with pressure dressings. Such dressings can often be left in place twelve or fourteen days. The closed treatment which is the tanning or eschar method, is particularly indicated in extensive flash or second-degree burns of the trunk. This method is recommended only if the following conditions are present: if not more than twenty-four hours have elapsed if the burned area has not been grossly contaminated, if strict surgical asepsis is employed in the preparation of the burned surface and if coagulation is rapidly accomplished that is, by the combined use of tannic acid and silver nitrate. The method of tanning described is the same as that given in the original edition of the pamphlet.

In the new directions additional emphasis is placed on masking of both the patient and his attendants, to minimize the danger of secondary infection.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

LAMPREY — ALICE CHESLEY LAMPREY, M.D., of Exeter, died June 30. She was in her eighty-second year.

Dr Lamprey received her degree from Tufts College Medical School in 1900. She was a member of the New Hampshire Medical Society.

Her husband and a sister survive.

Tuberculosis, other forms	19	23	30
Typhoid fever	1	2	4
Undulant fever	4	1	4
Whooping cough	537	970	757

Meningococcal meningitis, while still at a figure nearly twelve times the seven-year median and still surpassing all records antedating March of this year, is dropping decidedly, with only 94 cases reported, compared with last month's 140 and the previous month's 130 cases.

Thus far, 1943 has seen scarlet fever at a notably high level. Since March, 1941, the monthly figures for this disease have been consistently higher than those of the previous year. In 1942, the increase became marked. The highest point in thirty-seven years was reached in April of the current year. During May, however, a significant drop is apparent, the monthly figure being the lowest since January. As regards distribution of cases, it is about as one would expect, in that the bulk of the cases occurred east of Worcester in the area of greatest population. Springfield, however, has had an unusual number of cases of scarlet fever, which reached a peak in March and has been dropping sharply since then.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Boston, 1; total, 1.

Anthrax was reported from: Haverhill, 1; total, 1.

Diphtheria was reported from: Fall River, 1; Lowell, 1; Melrose, 1; Somerville, 1; total, 4.

Dysentery, bacillary, was reported from: Boston, 8; Medford, 4; total, 12.

Encephalitis, infectious, was reported from: Leicester, 1; Needham, 1; Waltham, 1; total, 3.

Malaria was reported from: Camp Edwards, 1; Fort Banks, 8; Fort Devens, 2; New Bedford, 1; total, 12.

Meningitis, meningococcal, was reported from: Arlington, 1; Attleboro, 1; Auburn, 1; Bellingham, 1; Belmont, 1; Billerica, 2; Boston, 30; Bridgewater, 1; Brookline, 2; Cambridge, 2; Camp Edwards, 7; Chelsea, 2; Charlton, 1; Easthampton, 1; Fairhaven, 1; Fall River, 1; Falmouth, 1; Fort Banks, 1; Fort Devens, 2; Framingham, 1; Hanover, 1; Haverhill, 1; Holyoke, 1; Hudson, 1; Lawrence, 1; Leominster, 1; Lowell, 2; Malden, 3; Melrose, 1; Methuen, 1; Milford, 1; Milton, 1; New Bedford, 1; Newburyport, 1; Quincy, 3; Revere, 1; Rockport, 1; Somerville, 1; Spring-

BOOK REVIEWS

The Medals of the United States Army Medical Department and Medals Honoring Army Medical Officers. By Edgar E. Hume, M.D., D.P.H., D.T.M., LL.D. 16", paper, 169 pp., with 23 plates. New York: The American Numismatic Society, 1942. \$3.00.

Colonel Hume, a well-known historian of the Medical Department of the United States Army, has listed all the medals that have been issued honoring army medical officers. With each description of the medal itself is contained a brief note about the individual who established the gift and the man honored by the medal. There is also considerable historical information in regard to the founding of the Medical Department of the United States Army and the establishment of the Army Medical School, the Army Veterinarian School, the Medical Field Service School and other departments, including the Army School of Nursing and the School of Aviation Medicine. Each medal is illustrated.

This record is invaluable as a historical document and contains considerable material not easily available in other form. The book is a complete, carefully documented account, which should be of interest to a wide audience and should serve as a reference book in every medical library. Medical historians and librarians are greatly indebted to the American Numismatic Society for making this monograph possible.

The Answer Is . . . Your Nerves. By Arnold S. Jackson, M.D. With a chapter by The Rev. Edwin O. Kennedy. 12", cloth, 197 pp., with 10 illustrations. Madison, Wisconsin: Kilgore Printing Company, 1942. \$2.00

This is a popular account of nervous diseases as seen in a large clinic and also in private practice. The book is well written and adequately covers the field. Of particular value are the striking and often amusing illustrations that accompany the text. It is a useful, small publication, which should be widely read, both by physicians and their patients.

NUMBER 5

DIAPHRAGMATIC (HIATUS) HERNIA*

A Clinical Study

W. RICHARD OHLER, M.D.,† AND MAX RITVO, M.D.‡

BOSTON

DURING the last thirty years there has been published an extensive literature based on the study of large series of cases dealing with the signs, symptoms and differential diagnosis of hiatus hernia. Despite this, clinicians have been slow to appreciate the full importance of the disease, especially in the differential diagnosis of certain thoracic and abdominal conditions.

Any such point of view is not without medical literature to the contrary. As early as 1853, Bowditch¹ wrote a lengthy treatise on the subject of diaphragmatic hernia and reviewed the literature. The actual number of references in the literature was twenty-seven, beginning with the first reference to the disease made by Ambroise Paré in 1610. Bowditch carefully reviewed the symptomatology of the condition, which included most of the symptoms recognized today. Following the work of Bowditch, little appeared in the American literature until 1901, when Ingals² published an article entitled "The Diagnosis of Diaphragmatic Hernia." It is of considerable interest that the author mentions the following as the principal symptoms: dyspnea on exertion and sometimes on lying down, pain in the bowel, especially after a full meal and in cases in which the opening was small, and vomiting in many cases in which the opening was large.

PATHOLOGIC ANATOMY

Most observers conclude that all cases of diaphragmatic hernia are actually or essentially congenital in origin. Polley³ suggests that age and obesity are contributing factors. He quotes other factors set forth by Akerlund as follows: stretching

of the hiatus due to insufficiency of the surrounding muscle fibers, decrease in the amount of fat tissue in the esophageal ring, decrease in the elasticity of the elastic fibrous tissue about the hiatus, loosening of the connective tissue between the esophagus and the peritoneum and increase in intra-abdominal tension. In addition, Giffin⁴ and Vinson⁵ mention trauma or minor injuries; Ritvo⁶ stresses increased abdominal tension and enumerates various causes; Turner,⁷ and also Gaudrault and Chalmers,⁸ suggest the production of hiatus hernia by increased abdominal pressure associated with neoplastic disease. Finally, Weintraub and Tuggle⁹ mention the high incidence of diaphragmatic hernia in cases of duodenal diverticulum, concluding that if one congenital defect is found in the gastrointestinal tract, others are likely to be present.

SYMPTOMS

The symptoms of hiatus hernia may simulate any one of several conditions in either the anterior chest or upper abdomen. In describing this close relation Morton¹⁰ aptly uses the term "mimic." Large series of cases have been reported by Giffin,⁴ Hedblom,¹¹ Ritvo,⁶ Dunhill,¹² Morrison,¹³ Cowan,¹⁴ Bock, Dulin and Brooke,¹⁵ Harrington,¹⁶ Dwyer,¹⁷ Moersch,¹⁸ Jenkinson and Roberts,¹⁹ Polley³ and Jones.²⁰ Harrington²¹ states that the symptoms may begin at birth or any time during life, and Ladd and Gross²² call attention to the similarity of symptoms in children with those found in adults. In general, most authors agree that symptoms are more likely to occur in middle life, for reasons already stated.

Abdominal

From a review of certain articles in the literature (Cowan,¹⁴ Hedblom¹¹ and Harrington,²³ it appears that the commonest abdominal symptoms,

*From the Thorndike Memorial Laboratory and the Second and Fourth (Harvard) Medical Services, Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Assistant professor of medicine, Harvard Medical School, chief of Second Medical Service, Boston City Hospital.

‡Assistant professor of roentgenology, Harvard Medical School, visiting roentgenologist, Boston City Hospital.

listed in order of frequency, are as follows: epigastric pain, a feeling of distress after or during a meal associated with bloating, belching and heartburn, nausea, vomiting and regurgitation, night pain or pain in the recumbent position, dysphagia and hiccough. Various methods for the relief of symptoms have been advocated, chief among which are getting up and walking about, induced vomiting, use of the stomach tube, defecation or use of enemas, alkalies and belladonna. Bock, Dulin and Brooke¹⁵ mention the feeling as if a rib had slipped in the lower left chest, especially when the patient is bending forward. Ritvo⁶ states that the most significant complaint is a feeling of weight or pressure under the xiphoid, coming on during or shortly after eating and relieved by a hot drink or by walking about for a few moments. Polley³ concludes that there is no relation between the severity of symptoms and the type or size of the hernia, and Jones²⁰ is convinced of the importance of small hernias in causing pain.

Anterior Chest

The chest symptoms of hiatus hernia are frequently similar to those of heart disease, especially angina pectoris. Many observers (Harrington,²³ Dwyer,¹⁷ Healy,²⁴ Truesdale,²³ Weitzen,²⁶ Johnson,²⁷ Jones²⁰ and Hedblom²⁸) call attention to the importance of substernal pain in hiatus hernia, and to the fact that the pain may be agonizing and may radiate to the shoulder and down the left arm. Jones finds that substernal pain is more likely to occur in patients who have small hernias. He also mentions cases with substernal pain radiating to the left shoulder down the arm into the ring finger, and also points out that exertion, nervous tension and large meals are precipitating factors. Reid²⁹ describes a case of hiatus hernia occurring in a physician that simulated cardiac infarction. The detailed report of this case, with the various suggestions made by colleagues to explain the symptoms, is both interesting and instructive. In addition to substernal pain, many observers mention dyspnea and palpitation, especially in the recumbent position or after meals. Also, McGinn and Spear³⁰ describe a patient with a large diaphragmatic hernia who had a cor pulmonale and marked dyspnea. They suggest that compression of the lungs by the herniating stomach causes an acute right-sided heart strain.

Attempts to explain the cause of chest pain in hiatus hernia reveal some difference of opinion. Johnson²⁷ suggests that the cardiorespiratory symptoms are due to the pressure of the hernial contents on the vagus nerve as it passes through the hiatus.

Gilbert, LeRoy and Fenn,³¹ as a result of animal experimental work, found that distention of the stomach or peritoneal cavity caused a decrease in the blood flow through the circumflex branch of the left coronary artery, thus explaining attacks of angina pectoris in patients with distended stomachs. Jones,²⁰ in a careful study of the mechanism of pain in both angina and hiatus hernia, concludes that overdistention of the lower end of the esophagus or the herniated portion of the stomach, with or without associated esophagitis or gastritis, may be responsible for the production of anginal pain in any or all of its components.

COMPLICATIONS

It is generally agreed by various observers that hemorrhage is the most important complication of hiatus hernia. (Giffin,⁴ Bock et al.,¹⁵ Gardner,³² Moersch,¹⁸ Eusterman and Morlock,³³ Wilkinson and Adams,³⁴ Polley³ and Jones.²⁰) Concerning the actual cause of the bleeding there is some doubt. In a case reported in the Cabot Case Records,³⁵ bleeding was supposed to have been due to varices in the blood vessels of the gastric mucosa. Also, Bock concludes as a result of post-mortem study that congestion of the mucous membrane of the stomach presumably caused by increased venous pressure is the cause of the bleeding. On the other hand, Truesdale, Hunt and Leigh³⁶ claim that hemorrhage is due to erosion or ulceration of a portion of the stomach that has become incarcerated, constricted or fixed. These authors also discussed the role of obstruction as a possible complication and, later, Truesdale³⁷ debated the problem of the development of gastric ulcer and possibly cancer. The possibility that large hernial sacs may cause right-sided heart failure has been mentioned previously.

* * *

The above review of certain articles from the literature is sufficient to demonstrate the fact that since 1912 there has been considerable interest in the subject of hiatus hernia, and that the symptomatology and differential diagnosis have been well described. However, if experience over a period of years in a large general hospital is any guide, clinicians have been slow to include this condition in the differential diagnosis of upper abdominal and anterior chest disease.

Since it has been possible to collect from the records of the Boston City Hospital a series of 123 cases during a period of less than four years, the condition is not rare. In fact, more attention to symptoms may demonstrate that the abnormality is fairly common.

ANALYSIS OF CASES

One hundred and thirty-six cases have been reviewed—128 from the hospital records and 2 from the private files of one of us (WRO). In the following tables an attempt is made to classify the various symptoms and signs, together with important complications.

Jones²⁰ classified as small those hernias that do not exceed a maximum diameter of 7 cm. In the hernias classified as large in his series, at least one third of the stomach was involved. Lacking definite information regarding measurements in our series, we have accepted the roentgenologist's

TABLE 1 Size of Hernias

Size	No.	%
Small	58	43
Moderately large	17	12
Large (at least one third of the stomach herniated)	40	30
Unclassified	3	2
Total	118	100

description as and when given (Table 1), being careful to speak of large hernias only when at least one third of the stomach was herniated through the hiatus opening.

Of the 136 patients with hiatus hernia, 18 were considered to have a congenitally short esophagus.

In the group of associated diagnoses (Table 2), there are a number of conditions that may give rise to symptoms similar to those of hiatus hernia.

TABLE 2 Important Associated Diagnoses

DIAGNOSIS	No. of Cases
Diverticulum of esophagus	3
Cancer of esophagus	2
Peptic ulcer	7
Cancer of stomach	4
Diverticulum of duodenum	4
Diverticulosis of colon	7
Gall bladder disease: cholecystitis or cholelithiasis or both (diagnosed by x-ray or operation or both)	5
Total	32

Therefore, in the following discussion the 32 cases with important associated diagnoses are omitted, leaving a total of 104. The finding of 4 cases of diverticulum of the duodenum and 7 cases of diverticulosis of the colon is of some interest. Weintraub and Tuggle,⁹ in a study of 310 cases of duodenal diverticulum, found that 9 per cent of the patients had an associated hiatus hernia and 23 per cent an associated diverticulosis of the large bowel.

In general, symptoms fall into groups suggesting peptic ulcer, gastrointestinal malignancy, gall-bladder disease or heart disease. Realizing that an absolute differentiation cannot be made, the best

we can do is to group material according to predominant symptoms (Table 3).

Of the 9 patients without symptoms, 4 had small hernias and 5 had large hernias, with even distribution of at least two thirds of the stomach

TABLE 3 Classification according to Predominant Symptoms

SYMPTOMS	No. of Cases
Gastrointestinal	59
Gall bladder	23
Coronary	9
None	9
Total	104

Among the thirteen cases with symptoms suggesting coronary disease, one or more of the observers who saw these patients was of the opinion that 6 of the patients had definite coronary artery disease in addition to a hiatus hernia, and in one case this opinion was supported by suggestive electrocardiographic changes. Finally, it should be mentioned that in the 82 cases with symptoms suggesting either gall bladder or gastrointestinal disease, careful x-ray studies revealed no disease other than a hiatus hernia. Despite this fact, several patients in this group were unnecessarily submitted to surgery.

Table 4 lists the symptoms in 95 cases, regardless of the size of the hernia. An attempt was made to classify symptoms according to the size of the lesion but without clear cut differential data. It is to be remembered that hernial size may

TABLE 4 Distribution of Symptoms (95 Cases)

SYMPTOMS	No. of Cases

Unrelated to exertion	5

change from time to time and that a single observation by x-ray is not necessarily an accurate basis for a definite classification. At any rate, in the 13 cases with symptoms suggesting coronary disease, 5 patients had large, 2 moderately large, and 6 small hernias.

The symptoms in 95 cases were relieved as follows: by assuming the upright position, 13 cases; by the use of soda, 11 cases; by vomiting, 6 cases; by belching and by lying down, 3 cases each; and by defecation, 2 cases.

Among the 104 cases, there were 29 cases with mild hemorrhage, and 12 with gross bleeding. Only those cases are included that revealed an appreciable fall in hemoglobin level and red-cell count and at least a ++ guaiac test for occult blood in the stools. Cases listed as having had a gross hemorrhage include only those with a hemoglobin level of 50 per cent or lower. Consideration of hemorrhage in relation to the size of the hernia is of interest (Table 5). Of real impor-

TABLE 5. Hemorrhage in Relation to Size of Hernia.

Moderately large....	10	2	3
Large	27	9	1
Unclassified	24	6	4
Totals	104	29	12

tance, however, is the observation that bleeding of either mild or severe type is just as likely to occur regardless of the size of the hernia.

SUMMARY OF CLINICAL DATA

The typical symptom of hiatus hernia may be described as a sense of epigastric pain, distress and fullness coming on shortly after or during meals. Frequently this symptom is associated with nausea, vomiting, regurgitation, belching or a sense of burning, but not infrequently these symptoms are independent. Often there is difficulty in swallowing solid food, lack of appetite and associated weight loss. Very frequently there is epigastric pain or distress appearing at night or when the patient is in the recumbent position, but in most cases this pain is relieved when the patient assumes the upright position. For the digestive symptoms mentioned above, change in position may bring relief, but just as frequently soda gives relief, and occasionally a patient complains of inability to raise gas. There is often substernal pain or dyspnea or both — generally but not always unrelated to exertion. The pain may present a type of radiation similar to that of angina pectoris, but just as frequently its radiation is atypical. Furthermore, the patient with hiatus hernia may bleed. The bleeding may be of mild degree, in which event it may well explain the finding of anemia characteristic of chronic blood loss, or the patient may have a hemorrhage sufficiently severe

to endanger life. Finally, it appears from this study — although definite proof is lacking owing to insufficient data — that symptoms and complications are not related to the size of the hernia.

Such is a composite clinical picture of a patient with hiatus hernia as drawn from the records of the Boston City Hospital. In general, this picture corresponds with the many found in the medical literature.

X-RAY DIAGNOSIS

Since the manifestations of hiatus hernia are so variable and inconstant that clinical diagnosis is usually impossible, x-ray demonstration is necessary to establish the presence of the abnormality. In some patients routine x-ray studies of the esophagus and stomach suffice to outline the hernia. In the majority of cases, however, the lesion is very small or for other reasons difficult to visualize. In these cases it may require the utmost care on the part of the roentgenologist to prove the existence of the hernia.

In searching for an esophageal hiatus hernia, the x-ray examination should always begin with fluoroscopic observations without the opaque meal. A careful and thorough search is made for a gas-containing shadow lying at or slightly above the level of the diaphragm. This is of particular importance since in some cases the hernia reduces itself and disappears on ingestion of the opaque meal. Observations are first made with the patient breathing quietly, then in full inspiration and forced expiration. The frontal and oblique positions are used in the erect, prone and supine positions. Occasionally both gas and fluid are present within the herniated portion of the stomach, presenting a horizontal fluid level with an air bubble above the liquid.

When the opaque meal is administered, the fluoroscopic observations are best begun with the patient in the erect position. Each mouthful is carefully observed in its passage through the esophagus. The lower end of the esophagus may be tortuous and moderately dilated. Rarely, pressure of the hernia produces esophageal obstruction, with consequent dilatation. In patients with congenital shortening of the esophagus, the cardioesophageal junction is seen to be above the level of the diaphragm. The hernia in many cases fills partially or completely with the patient erect. However, it has been our experience that the great majority of hernias are not demonstrable in this position. Therefore, if the x-ray observations are carried out only with the patient upright, as is the case in some clinics, a large percentage of the lesions will not be visualized and the diagnosis will consequently be missed.

It is with the patient lying down that the hernia is most apt to be demonstrated and its size and shape best outlined. Deep, forced breathing, pressure on the abdomen, lowering the head of the table, filling the colon with barium or air, asking the patient to strain or cough—these or other maneuvers that tend to increase the intra-abdominal tension may be used to help visualize the hernia. Complete filling of the stomach with the barium meal is important. The patient must be observed in the prone, supine and oblique positions, no one position being optimum for all cases.

Although fluoroscopic observations usually serve better than x-ray films for the demonstration of the hernia, the latter should be made in every case. Occasionally the lesion is visualized only in the films and not during fluoroscopy. Spot films exposed during roentgenoscopy are now available in most clinics and are extremely helpful in the study of difficult cases. The hernia appears as a rounded or oval shadow in the posteromedial portion of the thoracic cavity just above the diaphragm. Rugal folds are demonstrable in the herniated portion of the stomach, extending through the esophageal orifice of the diaphragm. The size and shape of the hernia vary widely in different patients, and in the same patient at various times. Small lesions may be but a few millimeters in diameter; the largest may comprise half or more of the stomach. The hernia most commonly lies to the left of and anteriorly to the esophagus. With large hernias the esophagus may appear to be encircled by the herniated portion of the stomach. Cancer or ulcer may occur in the hernia or other parts of the stomach, and a careful search for other pathologic processes should be made in every case.

TREATMENT

Hiatus hernia may present no symptoms and therefore require no treatment. All observers are agreed that treatment is essentially medical, especially in patients with small lesions. A bland, high-vitamin diet, divided into four or six feedings, is desirable. Food should not be given before bedtime. Assumption of the upright position after eating or for a few minutes during the course of the meal is often helpful. In many cases sleeping at an angle of 45° has relieved distressing night symptoms. Various alkalies and antispasmodic drugs are frequently useful. Recently Levy and Duggan³³ have emphasized the psychic factor in the management of such cases. Surgery is indicated when medical measures fail to give relief, especially in patients having intractable pain or hemorrhagic tendencies. A large measure of relief may result from interruption of the left phrenic

nerve. On the other hand, surgical repair offers a complete cure, and the surgical technic of the procedure has been well standardized.

In our series, 4 patients had phrenic-nerve interruption and I was operated on for repair of the hernia, in all cases because of attacks of severe epigastric pain. In the 4 cases in which the phrenic nerve was interrupted, relief was either partial or temporary. In the single case of hernia repair, relief was permanent.

DISCUSSION

It is generally believed that hiatus hernia is congenital. It must follow that most patients have the condition for many years before exhibiting symptoms. Actually, in most cases, symptoms come at a period in life when one may expect the onset of symptoms of other conditions, all of which serve to complicate the study. The symptomatology and clinical findings of hiatus hernia are inconstant and variable, so that although the existence of the condition may be suspected by the clinician, it is usually impossible to make the diagnosis with certainty on the basis of the history and physical examination alone. Furthermore, many of the complaints in hiatus hernia are also present in other, commoner diseases. It is highly desirable, therefore, to establish a syndrome on which a definite diagnosis is tenable.

In obtaining detailed histories of a large series of cases, a group of symptoms that have been met in a small number of patients but that have proved extremely significant are the following: a feeling of fullness, pain or distress in the epigastrium or under the tip of the xiphoid, coming on with the ingestion of the first few mouthfuls of food. In some cases these symptoms are so severe that they necessitate the interruption of the meal. However, on leaving the table and walking about for a short time, the patient may experience a sudden disappearance of the complaints, often with a feeling of something dropping or giving way in the region of the lower sternum. He is then able to return and finish the meal in entire comfort. The explanation is doubtless that the food first ingested produces filling of the herniated portion of the stomach, with distortion, compression and complete or partial obstruction of the esophagus; on arising and moving about, the herniated portion of the stomach empties or reduces itself, with resultant disappearance of the symptoms. In the experience of one of us (M.R.), this is pathognomonic of hiatus hernia, and although it occurs in relatively few cases, permits a practically definite diagnosis. Rarely, patients with

cardiospasm or esophageal diverticulum may give a somewhat similar history. In these conditions, however, the relief is usually not produced by arising and walking about, nor is it so immediate and complete.

Inasmuch as the clinical picture of hiatus hernia is similar to that of other disease in the chest or abdomen, one must be entirely certain of the state of affairs before assuming that hiatus hernia is the only cause of existing trouble. Recently we have seen a case of hiatus hernia with severe gastrointestinal bleeding in which the first gastrointestinal x-ray examination revealed no disease other than the hernia. A repeated x-ray study, however, revealed a deep duodenal ulcer in addition to the hernia. The problem becomes all the more difficult when one tries to explain attacks of chest pain on this basis. Certainly a patient may have both coronary-artery disease and a hiatus hernia. It is only after very careful study and observation, therefore, that a single diagnosis is tenable. The possibility of hiatus hernia should never be forgotten, and its presence never overlooked. Nevertheless, in one's enthusiasm at finding an abnormality that can be demonstrated, one should not neglect the fact that other disease may be present the existence of which can be demonstrated only by continued study and observation.

SUMMARY

Hiatus hernia is sufficiently common and the symptoms are such as to justify its inclusion in the differential diagnosis of anterior chest or upper abdominal complaints or both.

The presence of hiatus hernia should never be overlooked, regardless of its size.

In any case of unexplained bleeding, the presence of hiatus hernia should always be considered, since bleeding may occur in any type of case.

The symptoms of hiatus hernia may simulate those of coronary-artery disease. The differential diagnosis here is a matter of careful clinical judgment after all the data have been assembled.

A clinical syndrome pathognomonic for hiatus hernia has been suggested.

A method for determining the presence of hiatus hernia by roentgenologic examination is presented.

PANEL DISCUSSION: CURRENT EPIDEMIC RESPIRATORY DISEASES IN CHILDREN*

CHAIRMAN'S INTRODUCTORY REMARKS

DR. CHESTER S. KEEFFER, Boston: I need not tell an audience of this kind that the respiratory infections are by far the most important group of illnesses that we deal with in medical practice. One sees them every day, and they always raise important and frequently distressing problems. We know that the respiratory infections are responsible for more disabling illness, for more absenteeism from school and from industry, than any other single group of disorders. Dr. Sisson has already referred to the fact that great strides have been made in treatment in the last few years, but very few advances have been made in prevention. So tonight the speakers are going to confine their remarks, in the main, to the treatment of these respiratory infections that are encountered every day.

ACUTE LARYNGOTRACHEOBRONCHITIS IN CHILDREN

JOHN A. V. DAVIES, M.D.†

BOSTON

I HAVE been asked to discuss what may safely be called a pediatric emergency. As you know, in past years acute laryngotracheobronchitis has carried a mortality of anywhere from 50 to 100 per cent.

When a physician is called in the dead of the night by a mother who says her infant has croup, the chances are that he has croup, and probably one is justified, after questioning her, in telling her to put the child in a room with warm steam and to give some suitable expectorant. However, it is important to bear in mind at the very outset that what seems to be a simple case of croup may actually be the start of something far more serious, that is, acute laryngotracheobronchitis.

One other disease that we see infrequently nowadays, diphtheria, should of course be borne in mind at the same time. But spasmodic croup usually follows a mild respiratory illness, most often begins at night, after perhaps a day out in the cold air, and as a rule quickly responds to steam and suitable doses of ipecac. The mother

should be warned that if the child does not respond in one or two hours, she should notify you at once, and you should examine the child carefully.

At the outset, it is often difficult to differentiate these conditions. However, acute laryngotracheobronchitis may usually be distinguished

FIGURE 1. Age Incidence in 38 Cases of Laryngotracheobronchitis and 18 Cases of Laryngotracheitis.

Of the former patients, 21, and of the latter, 8 were under two years of age.

from simpler and milder forms of respiratory illness by the fact that the symptoms are progressive and persistent. The child seems sicker. There is fever, and leukocytosis also. Therefore, if the symptoms do not respond quickly to steam and an expectorant, it is obvious that additional measures should be taken to deal with this threatening situation, and there is no doubt that the hospital is the place for such a child.

Before speaking more specifically of therapy, I should like to remind you of the pathology of the disease. One is not dealing with a simple laryngitis, nor with a simple tracheal irritation. As the name implies, the inflammation extends from the throat down to the bronchi, and possibly to the bronchioles. In the early stage of the

*Presented at a meeting of the New England Pediatric Society held on March 24, 1943, at Longwood Towers, Brookline, Massachusetts.

†Assistant professor of pediatrics, Harvard Medical School; staff bacteriologist, Children's Hospital.

disease, one encounters inflammation and marked swelling of all these tissues, so that the airway is restricted. Later on, if the disease progresses, and especially if certain organisms of which I shall

TABLE 1. *Bacteria Recovered on Repeated Cultures in 33 of 38 Cases of Laryngotracheobronchitis.*

ORGANISM	NO OF CASES	PER CENT

speak in a moment are present, necrosis and sloughing of the membrane and plugging of the bronchi may develop with resultant atelectasis and emphysema, and possibly pneumonia. The process

throat culture was taken, — not only in the trachea and the lungs but also in the blood stream. I have emphasized the bacteriology because the tendency nowadays is to treat specific organisms in a specific way.

Standard treatment at the Children's Hospital involves teamwork between the physicians, the nursing staff and the laboratory. We have decided that the hot steam room is not so good as a room in which we have a cold humidifier and in which the temperature is kept at a level of approximately 70 to 75°F. We think that the hot room is uncomfortable to the patient and to the attendant as well. We avoid unnecessary examinations and treatments. However, we believe that it is important, having placed a child in this humidified room, to obtain the proper cultures from the throat or trachea. We also like to get a blood culture, because now and then the invading organisms are more clearly identified by this method. However,

TABLE 2. *Bacteriology in Cases of Laryngotracheobronchitis according to Age.*

ORGANISM	UNDER 2 YEARS			OVER 2 YEARS			ALL CASES	
	PURE CULTURE	MIXED CULTURE	TOTAL	PURE CULTURE	MIXED CULTURE	TOTAL	NO	PER CENT
Beta hemolytic streptococcus	2	5	7	6	2	8	15	45
<i>Staph aureus</i>	4	10	14	0	1	1	15	45
Pneumococcus	1	4	5	2	0	2	7	21
<i>H. influenzae</i>	0	3	3	0	1	1	4	12

is widespread, and no one portion of the respiratory tract is involved.

Figure 1* will remind you of the age incidence of this disease, showing that in the majority of cases the disease occurs during the first two years. Indeed, almost 50 per cent of the patients are two years of age and under.

Table 1 shows the bacteria that invade the respiratory tract. I show this because there has been a tendency to consider the beta-hemolytic streptococcus as the only organism involved, whereas *Staphylococcus aureus* and the pneumococcus are also frequently present, as well as *Haemophilus influenzae*. Table 2 is even more illuminating. In patients under two years of age, the staphylococcus is more frequently found in pure culture than is the streptococcus; after that, the streptococcus appears more important. From Table 3 it is apparent that among the autopsied cases *Staph. aureus* was also important, and that in all the fatal cases the children were under two years of age. The streptococcus and the pneumococcus were also recovered, but the staphylococcus appeared in every case, — except one in which only a

undue measures are not taken to obtain these cultures, especially when the child is precariously near the borderline between life and death. From this point on, the procedure is largely a matter of the skill and judgment of the attending physician.

On the way to the hospital, if an ambulance is employed, it is well to make sure that one has some oxygen at hand. In case the child's airway becomes completely blocked off, which sometimes happens when a child is taken from the warm home out into the winter air, a life may be saved if the accompanying physician inserts a Mosher tube into the trachea.

Having made the decision to bring the child to the hospital, it is important to put a capable laryngologist on the alert and tell him he may be called to do something for the child. What he does depends a good deal on his experience and the progress of the patient. From observation of the course of events at the Children's Hospital, I believe that in most cases tracheotomy is probably the operation of choice, if operation is necessary. It usually provides permanent relief from high obstruction. It enables one to insert a catheter and aspirate the pus and some of the exudate from the upper bronchi and lower trachea.

*For Figure 1 and Tables 1, 2 and 3 I am indebted to Dr Charles H Cutler and Dr Charles F Ferguson

On the other hand, the intubation tube tends to cause necrosis of the larynx and trachea and is sometimes coughed out, leaving the child in the condition in which he began.

I emphasized the bacteriology of the disease because we now have the assistance of the sulfonamides.

midex and penicillin. Since one is dealing with different organisms, not exclusively with the streptococcus, sulfathiazole or sulfadiazine may well be started on the way to the hospital. At present, penicillin is not available for general use. The dosage of the sulfonamides will be discussed later, but it should be emphasized that a full dose should be given early.

Oxygen administration is probably elective in some cases, although it should be used when cyanosis is present. It may be necessary to give it by nasal catheter. If infants under two years of age do not respond in a reasonable time to sulfonamide therapy and general supportive measures, a transfusion of blood from an adult donor should be considered, in the hope of providing certain unknown factors that the infant does not have and

that some adult may possess. Transfusions seem to help some infants with staphylococcal infections.

The question arises whether one should give other drugs, such as ipecac. I should say, No. Morphine and atropine are absolutely contraindicated, since morphine suppresses the respiratory effort, and atropine dries the secretions, already too tenacious, and thus tends to plug off the respiratory tract.

A last point concerns fluids. We try to give fluids in moderate amounts, by mouth, even after tracheotomy. If the child's condition is too bad, we give them subcutaneously. It is important, however, to remember that in a situation like this one should avoid flooding the patient with fluids because the respiratory tract is already seriously embarrassed and adding a great deal of fluid to the circulation may increase the edema fluid in the bronchi and bronchioles and cancel all that has been gained by the previous treatment.

THE DIAGNOSIS OF VIRUS AND BACTERIAL PNEUMONIA IN CHILDREN

MAXWELL FINLAND, M.D.

BOSTON

THE TERM usually applied to acute infection of the lung, other than lobar pneumonia, is "atypical pneumonia." If I were to enumerate the various terms that have been introduced in recent years as synonyms for or forms of atypical pneumonia, my time would be up before I finished. In general, the term "virus pneumonia" is loosely used to express the desire of the physician to approach an etiologic diagnosis that he cannot make.

I shall mention briefly some of the problems involved before one can rule out a definite etiologic agent, and then some of the known agents other than bacteria that may cause pneumonia. This will still leave a residue, which is bothering most of us more, perhaps, than those cases in which the etiology can be determined.

In the first place, atypical pneumonias are the ones predominating among infants, even when the causative organism is one which in older people produces lobar pneumonia, namely the pneumococcus. All other organisms produce atypical pneumonias, even in adults. Thus we have atypical pneumonias due to all bacterial agents in infants, and to all bacterial agents other than pneumococcus in young children, in whom the pneumococcus produces typical lobar consolidation.

†Assistant professor of medicine, Harvard Medical School, associated physician, Thayer Memorial Laboratory, and Chief of Fifth (Harvard) Medical Service, Boston City Hospital.

Pediatricians are only too well aware of the difficulties in arriving at an etiologic diagnosis in infants. First is the problem of obtaining proper materials for culture. Then again, multiple organisms are usually isolated from the nasopharynx or sputum in infants, and one is confronted with the difficulty of arriving at a conclusion concerning which of the organisms is actually causing the disease. Nowadays, the direct observations afforded by the Neufeld typing of pneumococci are of great assistance. Cultures of the material that is aspirated or is taken on a swab after encouraging a child to cough can frequently give a predominant organism, and this can usually be considered as the etiologic agent. Blood cultures are most helpful in bacterial infections.

It must be remembered that besides the pneumococcus, the staphylococcus is an important etiologic agent, especially in infants, in whom aspiration of upper respiratory contents is an important factor. The streptococcus is one of the foremost causes of the pneumonias that follow virus infections, such as measles. It is also found in the pneumonias that occur after whooping cough, and after other streptococcal infections, like scarlet fever, tonsillitis and septic sore throat.

The pneumonia produced by the streptococcus is characterized in infants and in young children by a severe type of illness that advances rapidly and is accompanied by a rapid accumulation of fluid in the chest and by extreme toxemia.

Staphylococcal infection of the lung is characterized by an insidious onset of a severe illness. There is a purulent or perhaps pinkish sputum representing an admixture of pus and blood. There is usually a severe tracheobronchitis. The course of the disease is characterized by multiple cavities in the lung, and the tendency in young children to produce abscesses that rupture into the pleura, giving rise to pyopneumothorax. Staphylococcal pneumonias occur most frequently after influenza or following aspiration in debilitated infants and children.

The influenza bacillus may cause severe infections in the lung, particularly during epidemics of clinical influenza. It is also characterized by a lesion in the trachea and bronchi and by a hemorrhagic type of bronchopneumonia that is sometimes seen in the fulminating form of a staphylococcal pneumonia.

In infants, the factor of inhalation of foreign substances, including their own upper-respiratory secretions, is important in establishing lesions in the lower respiratory tract. Foreign bodies producing or predisposing to severe and recurrent pneumonias must always be borne in mind. Any

of the common pyogenic bacteria can cause pneumonia under proper circumstances.

Of the nonbacterial agents, the commonest is the virus of influenza, which is capable of producing various lesions in the lung. It may also predispose to severe bacterial infections, particularly with the staphylococcus or influenza bacillus, and sometimes with other organisms, such as the streptococcus. The latter is likely to produce the post-influenzal pneumonias if streptococcal infection happens to be prevalent, or in wards where streptococcal infections occur. The pneumonia would then be characteristic of the streptococcal type.

The psittacosis virus produces a disease in human beings almost exclusively after contact with exotic birds. Recently a good deal of attention has been focused on this virus and other closely related viruses that occur in many species of birds, including certain domestic birds, such as street pigeons and domestic fowl. The disease caused by these viruses is termed "ornithosis." These agents are extremely interesting and have other relatives in the virus family, many of which, under certain circumstances, may produce pulmonary lesions and others of which are not known to produce pulmonary lesions. The diagnosis of psittacosis or ornithosis in the absence of a history of definite contact with birds is difficult. Even with such a history the diagnosis is sometimes questionable, because of the wide variety of strains that can give immunologic reactions with these related viruses.

A number of other viruses have been isolated from cases of atypical pneumonia, mostly in adults. Presumably similar cases occur in infants and young children, since there are many reports of their occurrence in small outbreaks among adolescents. One group of these viruses produces pneumonia and meningitis in mice and has been called "meningopneumonitis." Another virus has been isolated by inoculating material from human beings into cotton rats. Still another virus can be isolated only by inoculation of the mongoose, a rodent that is native to Jamaica and is not available in this country.

There are many other viruses, one of which occurs in mice, that are also closely related to the viruses of psittacosis and meningopneumonitis. A virus has been recently described that has been transmitted from kittens to human beings; this virus produces a characteristic pneumonia in young kittens, but not in adult cats.

There are other possibilities. There is Q fever, which in America has been shown to be the cause of endemic cases as well as small outbreaks of pneumonia. In Australia the agent of Q fever

produces a disease simulating influenza, and it has not been recognized as producing pneumonia there. The agent is presumably identical with that of American Q fever, both are rickettsias.

In addition to these viruses, there are others that may also be associated with lesions in the lung, presumably due to these nonbacterial agents. For example, epidemic typhus fever and South African tick fever are known to give pulmonary lesions that are similar to the pneumonias produced by other viruses. Lymphocytic choriomeningitis may also do this.

The important point is that after one tries to identify the etiologic agent with all those I have mentioned, one has identified only a small proportion of the pneumonias that are not due to bacteria. In general, the recent tendency has been to make a diagnosis of virus pneumonia when a person has been treated with a sulfonamide drug and fails to respond to it. However, one must remember two things. In the first place, even the common bacteria that are known to respond are sometimes resistant to the action of sulfonamide drugs. This is occasionally true of the pneumococcus, but resistance of pneumococcal pneumonia to sulfonamide therapy cannot be said to be a common phenomenon. Secondly, it is to be remembered that pneumonia due to organisms like the streptococcus and staphylococcus requires prolonged and intensive treatment. Thus, if one starts out with a mild infection that one is trying to treat with small doses, and the patient becomes suddenly severely ill, one may assume that one is dealing with a virus pneumonia that has not responded, which actually one is dealing with a severe staphylococcal or streptococcal pneumonia that has been inadequately treated.

There are other diseases, particularly of infants that are suspected of being of virus etiology owing to the pathological picture. There was an epidemic disease among the newborn in Minnesota in which intracellular inclusions have been demonstrated both in the lung specimens and in materials obtained from the throat. It is also true that if one examines the lungs of children who die of whooping cough, a large percentage of them have intranuclear inclusions in the epithelium of the bronchi. What relation these inclusion bodies have to the etiology of whooping cough on the one hand, or to the pneumonia of which the infants die on the other, is not altogether clear.

There are other conditions from which infants die, as, for example, malnutrition and other debilitating diseases, in which intracellular or intranuclear inclusions, or both, are found at autopsy. The relation to the fatal illness or to the pneumonia that may be present is difficult to evaluate in such cases.

THE USE OF SULFONAMIDES IN THE TREATMENT OF RESPIRATORY INFECTIONS IN CHILDREN

CHARLES A. JANEWAY, MD*

BOSTON

THE chemotherapy of the common respiratory diseases of children presents many difficulties that one does not encounter in dealing with adults. One hears quite frequently somewhat intolerant remarks concerning practitioners who use sulfonamide drugs indiscriminately. I think that all those who do much work with the sulfonamides feel strongly against the indiscriminate use of the drugs, but in my brief few months in pediatrics, I can sympathize most heartily with those whose job it is to see children in the home and to decide with what types of infection they are dealing.

The last speaker, who probably knows as much about this subject as anyone in the field, has shown us how complex the problem has become. The job of the person seeing a sick child in need of the various etiologic agents is often extremely difficult, and one can hardly blame doctors for using these drugs almost indiscriminately, since in many cases they are effective. However, I consider that a defeatist attitude, and one that should not be encouraged, because there are definite indications and contraindications for their use. Children and adults got well before the days of chemotherapy. One should not let enthusiasm for a new therapeutic agent run away with one every time a person becomes ill.

What are the indications? They boil down to evidence of an acute bacterial infection of the respiratory tract that is obviously spreading and is a serious or potentially serious one.

We know that respiratory infections are due to two types of agents in general, and frequently the two agents act together. On the one hand are the viruses, on the other are the bacteria. One can make a fairly good generalization of the respiratory diseases, namely, that the sulfonamides are fairly effective against almost all the bacteria that cause respiratory infections, with the possible exception of the staphylococcus. Nevertheless they are singularly ineffective against the virus agents that often give the way for the bacterial infections, or may be the sole cause of the infection.

Therefore, anyone using the sulfonamides should try to bear in mind this question, What are the bacterial infections of the respiratory tract? And this, also, should be borne in mind. If the child shows by his clinical picture that he is suffering from a bacterial infection, how serious is that

*Assistant professor of pediatrics, Harvard Medical School; visiting physician, Children's Hospital; senior associate in medicine, Peter Bent Brigham Hospital.

infection? For every bacterial infection does not need to be treated with a sulfonamide: only those that are actually serious or potentially serious require it.

What signs does one have? Perhaps the first that is of considerable help is gained by just looking at the child. How sick is the child? For example, an ordinary cold may make a child extremely uncomfortable. He may have an obstructed nose, or a cough and he may be hoarse and have a little croup; but he is not apt to have a temperature of 104 or 105°F. and be prostrated, with a marked diarrhea, vomiting or other signs of general toxicity. One cannot get away from the fact that the person who can use the sulfonamides wisely is the best doctor. One cannot lay down rules for the use of these therapeutic agents that will work for an automaton. One has to use judgment. Therefore, the first question is, How sick, really, is the child? Secondly, are there any signs of invasion? Bacteria that are localized are no great menace. It is the bacterial infection that spreads that menaces the child.

The spread in the respiratory tract is easily seen. The infection first spreads to the sinuses, which become tender and fail to transilluminate. Then there are the ears, the commonest site of all. The patient develops an acute otitis media, possibly with swelling of the mastoid process, and mastoid tenderness. A site equally common is that of the lymph nodes that drain the area. If these become swollen and tender and increase visibly in size, obviously there is an infection spreading beyond the ordinary bounds of the upper respiratory tract. The lungs, again, are a site of spreading infection. However, as already pointed out, invasion of the lungs may be purely of a virus nature.

Regarding general signs, fever, general toxicity and leukocytosis are gauges both of the severity of the illness and at times of its nature. Unfortunately children, as I have learned to my distress in the last few months, do strange things, whereas adults react more regularly. As a generalization, to which many exceptions may be taken, the virus infections of the respiratory tract are accompanied by a real leukopenia. The white-cell count, in the face of a fever, fails to go up, and even goes down. On the other hand, bacterial infection may produce a queer reaction in the bone marrow, associated with a fall in the white-cell count instead of the usual rise, which when present is a helpful sign of bacterial infection.

Having considered all these things, one admits that the child is very sick but does not know what is the matter with him, except that he has an infection of the respiratory tract. He has a cough

and the eardrums are a little injected; the throat is red, and the temperature is 104°F.; he is prostrated, vomiting and refusing food, and he is fussy. I think that under those circumstances anyone would be foolish to suppose that he runs a greater risk by giving the child the sulfonamides than by failing to do so. My own philosophy is to take the bull by the horns. If I were worried about the patient, I should go ahead and give the sulfonamides a trial. In about two or three days one will be able to determine whether any effect has been produced. If one undertakes to give the child a trial of chemotherapy, he should be sure to give the child enough drug so that it will mean something. Chemotherapy should, in my belief, either be fairly intensive or should not be employed at all. A little chemotherapy for a doubtful situation is one of the worst abuses to which the sulfonamides have been subjected. It does the patient no good and the physician is up in the air at the end of three days, not knowing whether the child is sick from the sulfonamides or from the infection, or whether the sulfonamides have done him any good. He is about three days worse off than before he started.

What are the complications associated with the use of the sulfonamides? First, there are the toxic reactions to the drug, for which the child has to be watched closely. Secondly, there is the possibility that the child may become sensitized and thus will be in for trouble when he subsequently needs the drug for a much more serious infection in the future.

What does one have to watch in the child to whom one gives chemotherapy? If it is given fairly intensively and early, and as soon as the infection is brought into control the dosage is lowered, the toxic reactions one has to fear most are those involving the kidneys. A child's urine should be examined for the presence of red cells, indicating damage to the kidneys, and the mother should be instructed to try to get some idea of how frequently the child is voiding. The blood has to be watched to a certain extent. Hemolytic reactions are rare with the new sulfonamides. Depression of the bone marrow with agranulocytosis usually does not develop until after ten to fourteen days of chemotherapy. Sensitization with fever and rash is most apt to occur in the second week. One's idea should be to treat the child intensively in the beginning, and get him off chemotherapy, if possible, before serious toxic reactions are likely to occur.

What should be done before chemotherapy is started? I should like to re-emphasize the fact that, although cultures are not always possible in the home, bacteriologic study of infections is just

as much a part of the study of the infected child as listening to the chest or looking down the throat. Certainly, in any seriously ill child or adult, the best cultures that can be obtained should be taken before chemotherapy is instituted, not because it may be impossible to get positive cultures after several days of therapy, but because by that time it may be important to know in a short space of time what the infecting organism is. If one has to wait twenty-four hours for the laboratory report, when a child is desperately ill, a fatality may result. Knowing what type of infection is present puts one in a relatively strong position. One has all the facts, as best he can get them. The cultures may not be too satisfactory, but at least one has made an effort. The blood culture in any seriously sick, hospitalized child should be taken, if it is humanly possible.

What drugs can be used? Obviously, sulfadiazine is the most satisfactory of the sulfonamide drugs, it disturbs the child, as well as adults, much less in every way. Its sodium salt can be given parenterally with great ease, and therefore is the ideal drug. However, one might as well be forewarned. It may not be possible to buy sulfadiazine much longer—it is just one of the short ages, like butter and coffee, that we may have to get used to. It should be remembered that all the infections that respond to sulfadiazine respond to sulfathiazole. It is my practice in urinary tract infections, which are out of the field of this discussion, to use sulfathiazole. That means that one does not use sulfadiazine for everything, and thus can save it for the serious conditions, which are usually the respiratory diseases.

Sulfathiazole can be used in the same doses as sulfadiazine, with the single exception that one must remember that sulfathiazole is much more rapidly excreted, and thus it is more difficult to maintain an adequate concentration in the child by its parenteral use without getting renal complications.

Finally, there is the question of how much to give. I should like to re-emphasize a single point: do not give chemotherapy until you have made up your mind, on the basis of what you see, whether or not the child has a severe infection. If so, use it. And use enough. That does not mean too much. We have had the pendulum swing both ways. First, people gave too little, then they began to use such large doses that many children developed toxic reactions. One has to remember that the kidneys are the site at which sulfathiazole and sulfadiazine can produce their immediate and early toxic effects. It is especially true of children that when they have a severe infection, they may be quite dehydrated. It is dangerous to push

too large doses into dehydrated children, being sure that adequate fluid is administered to maintain a good flow of urine.

The dosage in general, if one goes by thumb, is approximately 1 gr per pound first twenty-four hours in any serious infection. If a child is seriously ill, one-half to three-fourths of this amount is given as an initial dose. If the child has pneumonia, the initial dose is $\frac{3}{4}$ gr per pound and then 1 gr per day per pound divided into four or six doses, whichever is most convenient. A day or two after the child's temperature comes down to normal, this can be cut down to half a gram per pound, and kept up a few days until the infection is obviously well under control.

Sodium sulfadiazine can be given in 5% solution by clysis under the skin, and it can be used in such concentrated solution administered by syringe quite readily. In infection, where vomiting is present, this is satisfactory. These drugs cannot be given rectally by rectum. With sodium sulfadiazine, 5% solution is as high a concentration as I should use under the skin.

DISCUSSION

DR KEEFER: Dr DAVIES spoke about the treatment of acute laryngotracheal bronchitis. He told us of a disease that frequently starts abruptly, is seen frequently in children under the age of two years, associated with a variety of organisms, including streptococcus, staphylococcus and pneumococcus. He also told us that one should not use morphine in the treatment of these patients. He emphasized the importance of a humidified room with a temperature of 70 to 75°F. He was not in favor of cold in treatment, he advises the use of the sulfonamide oxygen and, in some cases, tracheotomy.

The first question that has been submitted answered in large part by Dr DAVIES in his paper is as follows: Discuss the treatment of acute laryngotracheal bronchitis, with reference to the effect of group tents and steam inhalations, to the use of cold, outdoor air and to the use of the sulfonamides. The criteria for tracheotomy and for intubation should like to have him define more clearly the indications for tracheotomy.

DR DAVIES: That is not an easy question to answer, since I am not a laryngologist. However, though intubation is still favored by some in this country, the trend is definitely toward tracheotomy. The measure of this sort must be undertaken. The laryngologists tell me that the trend is also toward medication and away from surgical treatment. The child is put at rest in a humidified room, sulfonamides are administered and in general, supportive measures are given. When that is well done, it is possible to avoid the number of children who require tracheotomy.

One difficulty with intubation is that the tubes cannot be inserted without considerable force.

the swollen tissues. As the child breathes and coughs, there is constant motion of the tube, which tends to cause necrosis and ulceration of the mucous membrane, with subsequent scar formation. Occasionally an operation is required to remove the tube.

Indications for tracheotomy itself are not always easy to define. Certain things must be borne in mind. One should not be guided by the child's voice. Some children have unaffected voices, and yet they may be in severe distress. One should be guided most of all by the general condition of the patient. How restless is the child? How cyanotic or fatigued is he? If the disease progresses and the child becomes weaker and weaker, a point may be reached where the child actually seems to relax. To the untutored eye, the patient may seem better. However, this change is a great pitfall, because actually it may be the stage before the end. Therefore, it requires some experience and considerable judgment to decide when tracheotomy should be done. In general, it should not be postponed until the child is completely exhausted, because death may occur quickly.

Tracheotomy, of course, is not without hazards. When it is done, the child usually gets considerable relief. It also enables one to insert a catheter and remove some of the secretions in the upper bronchi. I might add that now and then the bronchoscope is useful in removing thick crusts and secretions that plug the bronchi. In the presence of atelectasis, bronchoscopy may be advisable to relieve the obstruction.

DR. KEEFER: The next question is for Dr. Finland: "What is your opinion concerning the use of convalescent serum in the treatment of virus pneumonia?"

DR. FINLAND: That is a difficult question, and there is very little experience on which to base the answer. I might say first of all that there is no precedent to indicate that one might expect a good result from the use of convalescent serum, even if it is assumed that a virus is the etiologic agent. To my knowledge, there has not yet been demonstrated, either experimentally or clinically, any disease in which a cure has been accomplished by the use of the immune serum in a virus infection *after the infection has become established*.

I am certain that if there is anyone here who has seen a patient recover after receiving such convalescent serum, especially in large amounts, he would assume that the recovery was related to serum administration, and I suppose that in a single case that might be true. There is, of course, the possibility of modifying the disease, such as is supposed to occur in measles, and this cannot be excluded in virus pneumonia. However, I think one thing should be said: if convalescent serum is given, general experience with other infections indicates that fairly large amounts should be used. It would be interesting to find out whether such infections do respond. I hope that this will be tried under well-controlled conditions, and that it will yield some useful results.

DR. KEEFER: The next question is for Dr. Janeway: "How common are serious blood and kidney reactions with small doses of sulfadiazine, small doses being defined as ½ gr. per pound or less given for less than four days?"

DR. JANEWAY: I have answered this question indirectly before. I do not believe that anyone ought to begin treating a patient with an infection, except one in the urinary

tract, with a dose of that size. Therefore, this should not happen. However, one may say that serious kidney reactions would probably be rare with a dose of less than ½ gr. per pound per day.

Serious blood reactions, as I pointed out before, practically only occur after a period of ten days of chemotherapy. The size of the dose doubtless has some influence on whether a patient develops agranulocytosis. This is certainly commoner with large doses than with small ones. But I do not believe that the dose is the whole factor, by any means. I might toss the ball to Dr. Finland, who is much more experienced than I am. Do you think agranulocytosis is much less apt to occur with small doses, provided they are carried over a long period of time?

DR. FINLAND: I do not know whether it is more or less frequent, but it certainly does occur with small doses.

DR. KEEFER: I am going to give the next question to Dr. Davies: "Should sulfadiazine be given to every case of acute otitis media?"

DR. DAVIES: That is a hard question to answer. The practitioner who first sees the patient in the home has the most difficult choice and decision to make. In the first place, one is not always treating just the acute otitis. Furthermore, the age of the patient makes a great deal of difference. Very often the past history enters into the picture. If a child has been subject to repeated infections of the upper respiratory tract,—sinuses and so on,—one should be more ready to use the sulfonamides in the early stages of acute otitis media than in a child who, up to that time, has been in robust health.

I am sure that the general appearance of the nose and throat makes a difference. A child with large, bulky adenoids, a postnasal purulent discharge and possibly with swollen tonsils may require the early use of the sulfonamides.

Then there is the appearance of the ear itself. We are all familiar with the child who has had a mild cold and awakens at night with earache. What steps should be taken beyond the use of nose drops? If, in addition to the other considerations, the ear itself is acutely inflamed and bulges markedly, even though one may be dealing with a simple catarrhal condition, I am in favor of opening the ear and using sulfathiazole or sulfadiazine, taking a culture at the time the ear is opened.

The number of cases of mastoiditis seen nowadays is much less than formerly, and it is difficult to escape the conclusion that in some measure the reduced incidence is due to the wider use, in selected cases, of sulfonamides.

DR. KEEFER: The next question goes to Dr. Finland: "Will you discuss briefly the parenteral use of sulfonamides, the indications, the route of administration, the concentration and the question whether or not alkalies should be given along with sulfonamide treatment?"

DR. FINLAND: This subject has been covered by Dr. Janeway, but there are a few points worth emphasizing. The most important point I should like to drive home is that, whereas in general one should faithfully follow the instructions that come with the packages in which drugs are contained, because the instructions are usually approved by the Food and Drug Administration and also by the Council on Pharmacy and Chemistry of the Amer-

ican Medical Association, this is one exception. The Food and Drug Administration does not permit anyone to include in the literature directions for the use of sulfonamide drugs by the parenteral method, except as a sodium salt, given as a 5 per cent solution in distilled water. We used it once or twice that way, but we certainly have not adopted this method as a routine. We almost always give it in physiologic saline solution, chiefly because it is more convenient.

Several points concerning parenteral therapy should be emphasized. It should never be given in the same apparatus or together with blood, because clots may form when the sodium salts are mixed with whole or citrated blood. If one uses glucose solution, one should never permit it to boil in the presence of the drug, because the glucose inactivates the drug by combining with it to form a compound that is inactive when given parenterally. If given in distilled water, intravenously, it should be given only in a 5 per cent solution. In infants or in adults where it is not possible, not feasible or not convenient to use the intravenous route, or when intravenous injections are undesirable, the subcutaneous and intramuscular routes may be used.

British and Canadian physicians resort to the intramuscular use of high concentrations of the drug. There are two reasons for this. One is that distilled water because the drug is not so soluble in saline as in distilled water. Most of the sodium salts are not soluble in saline in more than 2 or 3 per cent concentration, at least, they do not stay in the solution very long. The British originally used sodium sulfapyridine in a 33½ per cent solution intramuscularly and noted few complications, although sloughs did occur, particularly when some of the material escaped in the subcutaneous tissues. Fewer complications have been noted with the sodium salts of other drugs than with that of sulfapyridine, but in general the intramuscular use of the high concentrations is not desirable, because of the possibility that high concentrations will get into the subcutaneous tissue and produce irritation. Since the sulfonamides are usually given parenterally to the sickest patients, who have frequently lost a good deal of fluid by sweating and vomiting, and who have had difficulty in taking adequate amounts of fluid by mouth, we like to use the drug in smaller concentrations—namely, in 0.5 or 1.0 per cent concentrations in saline solution. This makes it easy to administer and also makes it necessary to use a fairly large volume of fluid.

The indications for the use of any parenteral sulfonamide drug are the same as those for the drug itself, except that the patient finds it difficult or impossible to take it by mouth, particularly if he is vomiting a good deal, or in extremely ill patients where a few hours are important. In general, it is advisable to stop the parenteral use of the drug as soon as it is possible to give it by mouth. With the high concentrations that are attained soon after injection, the drug is brought rapidly to the kidney, where renal complications are much more likely to occur in the continuous parenteral therapy than when oral therapy is used.

The dosage of drug used parenterally is essentially the same as that given orally. The initial dose is identical. If sulfathiazole is used, it is preferable to divide the subsequent daily dose, if it is necessary to continue it parenterally, into three equal parts, and to give them every eight hours. If sulfadiazine is used it is possible to give half the daily dose at twelve hour intervals.

Concerning the use of alkalis, the incidence of untoward renal and urinary tract complications is somewhat less if the urine is maintained on the alkaline side. It is possible to maintain higher concentrations of the drug in the urine without precipitation in an alkaline urine, as compared with an acid urine, and if renal complications occur,—hematuria and so forth,—the administration of alkalis such as sodium bicarbonate by mouth or sodium lactate intravenously, is advisable. These alkalis are given to the point where an alkaline urine is obtained and maintained. Whether they should be used routinely is a question that depends a good deal on whether one may or may not give alkalis in large amount to the patient whom one is treating. They are not necessary in most cases with the usual dosage of sulfadiazine, provided the fluid intake and output are adequate.

DR KEEFER: I gather, then, that in giving the sulfonamides parenterally, the sodium salt in 5 per cent solution in distilled water, given intravenously, is *not* the method of choice. If it is dissolved in physiologic saline solution, 0.5 to 1.0 is as high as 3 per cent may be given.

The next question goes to Dr Janeway: 'What is the difference between the use of sulfonamides in children and in adults?'

DR JANEWAY: I do not think that the fundamental principles are the least bit different. The differences lie in the way children and adults react to disease. Children vomit more readily than adults do. Therefore, one has to resort to parenteral therapy more frequently with them than with adults. Children unfortunately void more or less at will, and not in response to the dictates of convention, therefore it is difficult to keep track of the fluid output. Anyone treating a child intensively has to be more alert in looking for renal complications. With an adult, all one has to do is to have the nurse collect the urine in twelve hour lots. This can be done in the home by using a quart milk bottle, and it is easy to see whether the output rises or falls. But with children it is not so simple. One has to depend more on the answers of the mother or the nurse, and more particularly on the examination of the urine, looking for red cells. The third thing, which I pointed out before, is that the white-cell count is a fickle guide whether or not one should use intensive treatment in children, because there are so many abnormal responses of children's blood to infections. However, I believe that, taken all in all, the differences between chemotherapy in children and in adults are not great.

DR KEEFER: Here are two questions for Dr Davies: 'What are the indications for the use of nose drops? What type of base should be used, oil or water?'

DR DAVIES: The latter question is easy to answer—water. But the indications for the use of nose drops are not quite so simple. I am quite sure that we use them too much. One might say that with a simple rhinitis nose drops are scarcely necessary. However, if the infant is having trouble in breathing at feeding time, some use of shrinking nose drops before feeding is worth while. If there is definite nasal obstruction, especially if there is a purulent discharge and evidence of sinusitis and otitis nose drops should be used.

It is hard to choose the types of nose drops, nowadays because there are so many. We start with ephedrine, 1

per cent in saline solution, sometimes increasing it to 3 per cent. There are various proprietary preparations on the market, some of which now incorporate sulfathiazole or sulfadiazine. But I shall pass the question of the addition of sulfonamides to nose drops over to Dr. Janeway. Personally, I believe that the sulfonamides are not necessary in nose drops, but I am open minded about it; possibly Dr. Janeway will have more definite opinions on the subject.

DR. JANEWAY: I am not open minded about it. I do not think that sulfonamides ever should be used that way. Drugs are coming in that may be effective in these solutions, such as penicillin. I can see no reason for putting the sulfonamides in nose drops, for the simple reason that they do not remain long enough to do any good.

When one is not open minded, one is apt to be wrong. However, I believe that the indiscriminate use of these drugs in nose drops is wrong. It is easy to sensitize people through the nasal mucosa and the skin, and the use of sulfathiazole in nose drops is just as bad as some other uses, such as in ointments for skin infections. The latter should not be used as a routine. In the first place, one can clear up impetigo with agents that are more definitely bactericidal than sulfathiazole ointment, which has to be put on every three hours to do any good. I have seen a number of cases in which sensitivity to the sulfonamides originated from the local use of relatively small amounts of the drug; the patients reacted when given the drug by mouth for more serious infections later on. That is particularly true of sulfathiazole, which is an excellent sensitizing agent, so far as we can find out. The incidence of sensitivity is high.

Since sulfathiazole will be used more in the coming year or two, it is rather important not to employ it in cases in which its value is questionable.

DR. KEEFER: Dr. Finland, will you say something about the problem of sensitization?

DR. FINLAND: This is a rather difficult subject. Certainly some men who are concentrating their efforts on the treatment of allergic children look with awe on those who hand out sulfonamides on the least provocation and even on those who use sulfonamides for all infections. They are afraid that these patients will die some day from a subsequent dose of a sulfonamide drug. At least, so it was said at a meeting of the Academy of Pediatrics.

There is no doubt that sensitization to sulfonamide drugs has occurred. As Dr. Janeway has mentioned, the worst offender is sulfathiazole. Such sensitization can occur at any time, particularly in a patient who has had drug fever or a skin rash or in the rare cases of jaundice. It may occur after the first dose, and may give a very vigorous reaction, with a high fever and chills. I know of a patient who had a high fever with jaundice, and almost a fatal reaction after a single dose of sulfathiazole given a few days after a similar toxic reaction that followed a course of sulfathiazole therapy.

How often sensitization occurs, how long it persists and whether it decreases with time or stays the same are questions that are difficult to answer at present, because the data available are extremely inadequate.

One thing is certain: in general, sensitization to any one drug, in the sense I have mentioned, does not mean necessarily sensitization to all other sulfonamides, and usually it is possible to administer a different drug at another time. If necessary because of the nature of the

infection, it is even possible immediately after the discontinuance of one sulfonamide drug to start giving another. Exceptions to this are probably extremely rare.

Sensitization is usually manifested by the occurrence of a fever or a rash, or both, but is sometimes manifested by other phenomena, such as the appearance of jaundice and enlargement of the liver, and in some cases by other reactions, such as those involving the central nervous system, which I have been fortunate enough not to encounter.

DR. KEEFER: General practitioners and pediatricians are using the sulfonamide drugs for almost every infection. They maintain that many children are being saved from otitis and its resultant mastoiditis, bronchitis, pneumonia and, when sulfadiazine is used, possibly meningitis. Some pediatricians are practical minded enough to give these drugs in proportion to the symptoms, and not in proportion to the body weight. Under these circumstances, illnesses are cut short, so that the drugs are used for only two or three days. Dr. Janeway, will you give one and, if possible, two sane reasons why this practice should not be followed in all early cases of respiratory disease?

DR. JANEWAY: This is a difficult question to answer. Many are saying that they give sulfonamides according to the extent of the respiratory infection, and they claim that the illness is short lived and does not lead to complications.

The only thing one can say is that the vast majority of respiratory infections are relatively mild diseases that subside without doing the patient any great harm, and it is questionable whether one should simply administer drugs on a perfectly blanket routine for any sort of infection. One might as well say that any time a person's heart goes faster than 100, one would give digitalis, and I think the reasoning would be much the same.

It is true that the majority of complications of the virus infections that cause the usual epidemic respiratory infections are bacterial in nature, and it is quite likely that a certain number of these can be prevented and diminished in severity by the administration of the drugs. However, against routine is the problem of sensitization, and the extent of that problem we do not fully know as yet. Also toxic reactions do occur. I have no doubt but that in a number of cases respiratory infections may last somewhat longer if chemotherapy is not given. But I prefer, in general, to use the sulfonamides for the treatment of infections rather than for their prevention. The administration of the sulfonamides does not do anything to the cold itself, provided it is a virus cold. In a certain number of colds due to bacterial agents it may be effective.

Concerning why the sulfonamides should be given according to the body weight rather than in proportion to the symptoms, the only answer is that we know definitely from a great body of laboratory evidence that one has to achieve a certain concentration of the sulfonamides in order to control bacterial infection. There is no doubt that a severe infection requires more sulfonamide for its control than does a very mild one. This is because in the mild infection the patient himself is controlling it to a very large extent, and all one does is add a slight deterrent to the bacteria, which enables the patient to overcome the infection. A severe infection is almost always due to a breakdown in the patient's resistance,

and the sulfonamides become the only agents that are really capable of controlling the infection until the patient rallies enough to get hold of it himself. So, to that extent, there is a rationale there.

On the other hand, one cannot cut down the dosage more than to a certain point and expect to get any results, unless one is using the drugs prophylactically. The only studies on this subject are those in the prevention of rheumatic fever. There, it becomes clear that relatively small doses, equivalent to 1 to 2 gm (15 to 30 gr) of sulfanilamide or sulfadiazine per day, are effective in the prevention of acute hemolytic streptococcus infection

and because of that, they are effective in preventing occurrences of rheumatic fever.

On the same reasoning, one might say, Give every patient with a cold these small doses of the sulfonamides. But my own belief is that one does not have to give the drug. Three quarters or more of the colds are taken care of in the usual course of events.

DR KEEFER I agree entirely with Dr Janeway. I do not believe that the sulfonamides should be given to every patient with a respiratory infection. I do believe that they should be given in accordance with the body weight rather than in accordance with the symptoms.

THE LATERAL VIEW IN THE ROENTGENOLOGIC DIAGNOSIS OF LESIONS OF THE COLON*

ELTON G. WISSING, M.D.,† AND ROBERT M. LOWMAN, M.D.‡

BOSTON

IT IS a well known fact that roentgenologic diagnosis of diseases of the colon, especially those of the sigmoid and rectum, is one of the more difficult branches of roentgenology. The lower colon has repeatedly been called the 'dark spot' of the gastrointestinal tract, and this statement has been especially true for the sigmoid and the lower descending colon, the rectum being easily accessible by other means of examination such as the proctoscope and, last but not least, the surgeon's examining finger.

It is, however, surprising as well as depressing to note how many lesions in these areas have been overlooked in the past, and how many are still missed in spite of numerous efforts to approach these regions in a more thorough and methodical manner. These efforts are highly important, since lesions of the lower colon are in the majority of cases malignant or premalignant.

Failure of the roentgenologist to detect early lesions has given rise to a pessimistic attitude on the part of the surgeon that is reflected only too well in the surgical literature. There we find comments such as the following, made by Bowman¹ as late as 1938: "A negative barium enema should not be regarded as diagnostic, since a majority of the tumors of the rectum do not show a filling defect. As a matter of fact, the majority of these lesions do show a filling defect, and the question here apparently is, What are the reasons for the failure of the roentgenologist to demonstrate these defects?"

The answer appears to be twofold: the peculiar anatomic conditions of the structures of the lower

gastrointestinal tract, and the failure to employ some or all of the helpful procedures that have been devised for the examination of these areas. Let us consider these two points.

Figure 1 reveals why a small tumor situated on the posterior wall of the colon (B) is so easily

FIGURE 1 Schematic Drawing Showing the Usual Relations of the Pelvic Segments of the Colon

A shows how a tumor in the upper rectal ampulla or in the sigmoid can be completely hidden in a posteroanterior view by overlying unaffected structures. In B a lateral view the rectum and sigmoid are shown in their entirety with no overlapping of the loops.

overlooked in the anteroposterior view (A). The tumor is entirely hidden behind the barium shadow of either the completely filled loop of colon or, worse, of two overlapping loops or, still worse, of both. Since the rectum is a wide, hollow tube with the sigmoid arising from it at an oblique angle, there is overlapping of loops of colon in a majority of cases. Knowledge of these anatomic difficulties has led to the development of several

Note that the defect is not visible in the posteroanterior view but well outlined in the lateral projection.

is claimed but which unfortunately are not so widely or so routinely in use as they should be.

One of these methods is the double-contrast enema. As early as 1910, Cole and Einhorn² advo-

routinely used in our x-ray department. The latter has proved particularly helpful in a large number of cases. All these procedures have been published and their importance emphasized, notably

in the more recent papers by Wolf,⁴ Stewart and Illick⁵ and Robins and Altman.⁶

We shall present the routine x-ray technic successfully employed in our department, typical case histories and accompanying illustrations.

A word should be said concerning the preparation of the patient. This is as essential a part of

After the enema is expelled, the patient is again fluoroscoped. If evacuation has been thorough, the remaining barium coats the colonic mucosa. If too much barium remains, fluoroscopy is repeated after further expulsion. A posteroanterior and a lateral film are then taken. In a majority of cases, it is possible in this way to gain a valu-

FIGURE 4. *Filling Defect of the Proximal Transverse Colon (Case 3—carcinoma).*

Note the improved visualization in the lateral view, in which the extent and character of the lesion are clearly shown.

the examination as are radiography and fluoroscopy. Without proper preparation, which essentially means cleansing, no adequate examination of the gastrointestinal tract is possible. For the colon, we use the following procedure: On the day prior to examination, 60 cc. of castor oil is given. One should insist on this medication unless a definite clinical contraindication exists. On the evening prior to examination, a high cleansing enema is given. The enema is repeated on the morning of the day of examination. The patient is then brought to the fluoroscopy room and put on the fluoroscopy table in the supine position. The enema is allowed to flow slowly into the rectum, and the patient is repeatedly rotated to the right- and left-oblique positions while being fluoroscoped. Of special value is the right anterior oblique position, which yields a better visualization of the rectosigmoid junction. A spot-film device allows one to take quickly small films of any suspicious area in the position best suited for its demonstration as determined by fluoroscopic examination. The entire colon is then filled to the cecum in the same manner, and a posteroanterior and a straight lateral film are taken immediately on the Bucky table.

able impression of the condition of the mucosa of the colon. If doubt concerning the diagnosis still remains, a double-contrast enema is employed. The colon is slightly inflated by air and films or spot films are taken. It should again be emphasized that all these examinations are done, and without exception should be done, under fluoroscopic control.

Whereas this procedure is not only time consuming but a little more expensive than others, at least four 14-by-17-inch films being taken, its value cannot be overemphasized.

The following 3 cases and accompanying radiographs are typical of the large number we have examined.

CASE REPORTS

CASE 1. The patient, a 60 year old man, had had loose stools all his life, recently with some gas and slight weakness but without weight loss. He had never had bloody or tarry stools. On physical examination, he appeared to be fairly well nourished. The head, heart and lungs were negative. The abdomen was slightly tender but no masses could be palpated. On rectal examination, nothing was found with the exception of a slightly enlarged prostate. A barium enema showed a constant annular filling defect in the sigmoid 18 cm. above the anal opening (Fig. 2). A colostomy was done,

and was later followed by a combined abdominoperineal proctectomy, with resection of the sigmoid. The pathological report was adenocarcinoma, Grade 2-3.

CASE 2. The patient, a 59-year-old woman, complained of increasing diarrhea,—instead of former mild constipation,—with no abdominal pain but with occasional small flecks of blood in the stools. She had been operated on for a pelvic abscess 1 year previously and had since lost 6 pounds. On physical examination, the head, chest and abdomen were essentially negative and no masses could be palpated. A barium enema revealed an organic filling defect of the sigmoid (Fig. 3), which proved to be an inoperable adenocarcinoma with extensive local and distant metastases.

CASE 3. The patient, a 45-year-old woman, had been well until 1½ years previously, at which time she had her first attack of diarrhea. These attacks had since occurred more frequently. She had nausea, indigestion, gas, a weight loss of 35 pounds and pain in the right upper quadrant of the abdomen, radiating to the back. On physical examination, the head and chest were essentially negative. An irregular abdominal mass could be palpated in the right upper quadrant. Roentgenologic examination showed a large organic filling defect in the proximal transverse colon (Fig. 4), which at operation proved to be a carcinoma. No liver metastases or adhesions were found. A transverse ileocolostomy was done.

Cases 1 and 2 are typical of many in our series. The extent and type of lesion are well shown in the lateral view in both cases. They could not have been diagnosed or even suspected from the

routine posteroanterior view, for the sigmoid in the affected area ran in a sagittal plane.

Case 3 differed from Cases 1 and 2 in two respects: the lesion was in the transverse colon, and it was visible also in the anteroposterior projection. However, comparison between the two views reveals the markedly increased diagnostic possibilities of the lateral projection. The exact extent of the tumor, the area of annular constriction and the shelving at the borders of the tumor are clearly demonstrated. The posteroanterior view, on the other hand, shows only indefinite disease.

SUMMARY

The advantages of the lateral view in the examination of the colon, with special reference to the sigmoid, are described, and an outline of the technic is given.

Three typical cases are described and illustrated.

ORTHOPEDIC SURGERY (Concluded)

WILLIAM A. ROGERS, M.D.*

BOSTON

Clostridia Producing Gas Gangrene

CLOSTRIDIA (spore-forming anaerobic gram-positive bacilli) are normally saprophytic. A number of them under suitable conditions may become pathogenic and produce gas gangrene, and one of them is the cause of tetanus, which is discussed in the following section.

Gas gangrene is a mixed infection, but certain of the clostridia are usually essential etiologic factors. Anaerobic putrefactive nonhemolytic streptococci may, however, produce an infection at present indistinguishable from gas gangrene.

Clostridium welchii (*Bacillus perfringens*), *Cl. septicum* (*B. oedematis maligni* or *Vibrio septicum*), *Cl. oedematis* (Novy) and *Cl. oedematoides* (Sordelli) are each capable of producing serious gas infection. One usually predominates in association with one of the others and also with one or several of the following less important clostridial pathogens that may augment the infection: *Cl. histolyticum*, *Cl. fallax*, *Cl. sporogenes*, *Cl. lentoputrescens* (*putrificum*) and *Cl. bifermens*. These latter, while contributory to the infection, do not alone seemingly possess sufficient aggressiveness to cause clinical gas gangrene and toxemia. These clostridia may be found in gas infection in association with many other bacterial species, both aerobic and anaerobic, including hemolytic streptococci.

Identification. Because fatal gas bacillus infection may become established with great rapidity, early etiologic identification is of the utmost importance. This cannot await cultural studies but must depend on local signs, although toxic manifestations may be strikingly significant. The mere presence of considerable numbers of large gram-positive bacilli in smears of wound exudate does not establish a causal relation. Local signs include the following: gas, evidenced by fine crepitus on gentle palpation about the wound, by bubbles expressed from the wound through the exudate, or by x-ray study; odor—putrefactive and mouse-like smells, the latter being seldom present but when found being diagnostic of infective gangrene

of muscle (Qvist²¹) and at once stamping the infection as serious; and local pain and edema, which may be conspicuous. *Cl. oedematis* when predominant may produce a lesion characterized by rapidly progressive massive edema with little or no gas or odor but with profound toxemia. In gas infection, toxic manifestations vary with virulence and toxigenicity and are therefore not dependable under all circumstances. There is an abrupt rise in pulse—the first sign of onset. This is especially noteworthy if accompanied by a rise of blood pressure. The temperature may be high (up to 105°F) in patients with good resistance, but slightly elevated in mild infections; if subnormal, with rapid, thin pulse and other signs of shock or hemorrhage, it is a bad prognostic sign.

Identification by cultural methods should be made immediately for subsequent specific antitoxic therapy, but this should not delay operative intervention or the immediate administration of polyvalent antitoxic serums.

Toxic factors. A number of toxins can be demonstrated, and considerable study has been made of their action in animals. Toxic effects in man, although they may be profound, have not been clearly defined (Wright⁷). Each of the group produces a specific antitoxin.

Source. Pathogenic clostridia are normal inhabitants of the intestinal tract of man and domesticated animals. They persist for long periods as spores in soil, especially where manure has been used as fertilizer, and in street dirt. However, analyses of the flora of fresh wounds, inflicted under widely diverse circumstances, commonly reveal the presence of clostridia capable of producing gas infection, often in considerable numbers. There is therefore ample justification for assuming the presence of pathogenic clostridia in such wounds regardless of the circumstances attending their infliction.

Pattern of infection. Gas bacilli are normally anaerobic saprophytes. They do not become pathogenic unless certain conditions peculiar to their needs exist in the wound. The condition fundamental for pathogenicity is a sufficiently low concentration of oxygen in the involved tissues to allow the spores to germinate, the bacilli to multiply, and toxins to be produced. This con-

*The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp., Springfield, Ill., 1942, Charles C. Thomas Company, 1942, \$5.00).

*Instructor in orthopedic surgery, Harvard Medical School; visiting orthopedic surgeon, Massachusetts General Hospital.

dition is apparently created as a result of impairment of the blood supply to the part either by local trauma, by vascular shock or injury or by vascular degenerative changes or by a combination of these.

Clostridial gas infections vary widely from innocuous and self-limiting to fulminating and hopeless. Other factors being equal, the severity of the infection is dependent on the tissue involved: those infections that are confined to cellular connective tissues are mild, and those established in devitalized muscle are apt to be grave and give gas gangrene its evil name. This distinction, recently re-emphasized by Qvist,²¹ must be clearly recognized. It is of great importance, both clinically and academically. Clinical differentiation between the two types of infection is definite.

In the first place, infections of cellular connective tissue by clostridia are probably much commoner than those in devitalized muscle. The inflammatory reaction is a cellulitis in general comparable with that of other organisms and noteworthy in respect to gas formation and gangrene. The infection may remain localized in the devitalized elements and cease when these have been exhausted; or it may spread slowly along fascial planes and subcutaneous tissues. So long as muscle is not involved as a rule the infection remains relatively mild: the mousy smell of muscle involvement is absent, and toxemic manifestations are not severe—the temperature is commonly not high, although the pulse rate is often considerably elevated. Although these signs are indistinguishable from those of early muscle infection, they are not comparable with the profound toxemia of a well-established infectious gangrene of muscle. This mild form of infection, often self-limiting and commoner in civilian than in military practice, may well explain the cures claimed for x-ray therapy in gas infections.

In the second place, when muscle is infected by gas bacilli, sepsis spreads rapidly and toxemia is profound. Under favoring conditions clostridial saprophytes present in the wound develop a striking virulence, which is quickly enhanced—within a few hours—by toxigenicity and invasiveness. Bacteria swarm through the injured portion of the muscle, destroying it. Next, the muscle distal to the wound, having a diminished blood supply but being still somewhat viable, is invaded. Extension occurs along the interspaces between fibers, which become choked with exudate and bacteria. The exudate is free of leukocytes unless the infection is complicated by pyogenic cocci. Disintegration of sarcolemma ensues, and the muscle fibers are then entered and disintegrated

by the bacteria. Fascial planes afford favorite avenues of extension. Invasion is considerably facilitated by thrombosis, which cuts off the blood supply, thus offering a new field for bacterial spread. Metastatic infection to distant muscle groups is sometimes seen. It occurs through septic embolism, but as a rule the clostridia cannot survive in the blood stream. Invasion proximal to the wound is not held in check for long. Uninjured muscle with an intact blood supply may provide a barrier for only a short time, often not long enough for the surgeon to intervene before it is too late. The infection may involve a single muscle—more commonly a muscle group—or a segment of a limb. The skin at the wound margin passes slowly and progressively through phases of redness, bronzing, duskiness and finally the blue and black of necrosis. The extent of skin gangrene is always far short of that of muscle necrosis. Gas formation may be apparent late or not at all. It is usually present to some degree, being revealed by gentle palpation as a fine crepitus, by x-ray examination or by bubbles expressible from the wound through the exudate. Gas formation may be profuse, at which time the margin of the crepitant area may show appreciable advance at 30-minute intervals and extend far beyond the infected region into healthy tissue. A mousy odor, often present, is diagnostic of gas infection of muscle. Rapidly spreading edema, more or less marked, is almost always one of the characteristics of the local sepsis. Clinical toxic manifestations include malaise, restlessness, apprehension and, later, prostration. An abrupt acceleration of pulse (to 120 or 130), accompanied by a rise in blood pressure, is very significant. The temperature may reach 105°F., but in patients with low resistance and a poor prognosis may be subnormal.

Cl. welchii and *Cl. septicum* are conspicuous producers of gas, and *Cl. oedematiens* of massive gelatinous edema. All these clostridia are profoundly toxigenic.

Uncommonly the muscle type of infection may be fulminating, with little or no demonstrable local edema, gas, odor or pain but with profound toxemia, accompanied by a cold pale dry skin, a pulse too rapid to count and a subnormal temperature. *Cl. welchii* has been shown to be responsible for this symptom complex; however, the same state may be produced by an anaerobic nonhemolytic streptococcus.

Management. Prevention of infection by a complete débridement, as discussed below, within four to six hours of wound infliction, supplemented by prophylactic serotherapy and chemotherapy,

largely solves the gas-bacillus problem. Animal experimentation supports the use of the sulfonamides in cases in which infection with *Cl. welchii* or *Cl. septique*—but not with *Cl. oedematiens*—is a possibility. Sulfanilamide is the drug of choice at present, 6 gm. being given orally as the initial dose, followed by 1 gm. every four hours for seven days; locally the crystalline form is sprinkled evenly over the wound surfaces, 0.1 gm. per square inch—but not over 10 gm. in all. The prophylactic use of polyvalent antitoxin in injured persons not sensitive to the serum is also indicated as a supplement to early débridement. The dose should be adequate and is specified on the container of the preparations in use.

The early recognition of established gas infection may be of vital therapeutic importance. To this end, patients with wounds involving muscle damage should be frequently checked—every two or four hours—for mousy odor and abrupt rise of pulse. Time is essential in many of these infections. When the diagnosis has been made, the appropriate surgical procedure is carried out without delay. Chemotherapy is begun at once, if it has not already been instituted, and in this regard much time may be saved by intravenous administration. Sulfathiazole is the present drug of choice. Polyvalent antitoxin is administered in large and frequent doses, both intravenously and in the muscle—by some being injected into the normal muscle about the wound. An initial dosage of four to six standard therapeutic doses is followed by two to four standard doses every four to eight hours until the infection is under control. When the responsible organisms have been identified in the laboratory, the corresponding specific antitoxins are used in place of the polyvalent.

The surgical procedure to be adopted depends on the type of tissue infected and on the nature and extent of the infection. Infective gangrene of muscle demands either radical extirpation of devitalized or necrotic tissue and the removal of foreign bodies, or amputation. Infections involving only the cellular connective tissues and not the muscle may be sufficiently dealt with by removal of sutures and a wide opening of the wound—possibly with simple incisions in addition. The mere presence of gas in a wound and numerous large gram-positive bacilli in a stained smear of the exudate does not justify amputation. The sacrifice of a limb superficially infected as in gas cellulitis is unnecessary and reprehensible. On the other hand, to withhold radical extirpation of an infected muscle or group of muscles in the belief that the infection is confined to the cellular tissues, is to court disaster. In extensive, rapidly spreading

muscle gangrene involving whole segments of a limb, amputation, if possible at a remote level, must be done promptly as a life-saving measure. Table 1 differentiates these two types of infection and their treatment.

All gas-infection wounds, whether the treatment has been simple incision, débridement or amputation, are left wide open. Meleney²²⁻²⁴ advocates a

TABLE 1. Signs and Symptoms, and Treatment, of Cellulitis and of Gangrene of Muscle.

CELLULITIS		GANGRENE OF MUSCLE
<i>Signs and symptoms</i>		
Relatively mild localized sepsis and mild toxemia		At first relatively mild and local, quickly becomes violent, spreading sepsis and profound toxemia
Odor putrefactive, but mousy smell/lacking		Mousy odor
No involvement of muscle at operation		Definite change in appearance of muscle, which may be hemorrhagic or discolored, may not contract normally on pinching, or may bleed abnormally slowly or not at all
<i>Treatment</i>		
Open wound widely, with incisions if necessary		Radical débridement, amputation (guillotine or, if favorable, open flap method).
Pack loosely and open with sulfanilamide pack or zinc peroxide dressing		Same as for cellulitis

loose packing, saturated with a creamy suspension of zinc peroxide—which must be of fresh medicinal grade—in sterile distilled water. The suspension is made just prior to use by adding the peroxide powder, sterilized in a dry sterilizer at 140°C. for four hours, to an equal volume of sterile distilled water. The wound is flooded with this suspension before the packing is placed, care being taken to reach all parts of it. The packing is covered with a thick layer of absorbent cotton soaked with distilled water, and the whole is covered with vaseline gauze to check evaporation. This dressing is changed daily. Trueta²⁵ advocates a loose sulfanilamide pack.

Immobilization of the limb is essential, and fluid balance (2000 to 4000 cc.) must be maintained.

Clostridium Tetani

Cl. tetani, a strictly anaerobic gram-positive bacillus with a terminal rounded spore, is at present recognized in nine different serologic types. These vary in their agglutination reactions, but all produce lethal exotoxins that are identical antigenically.

Toxic factors. The clinical manifestations of tetanus are due to the toxin produced by *Cl. tetani*. The disease in its typical form can be produced by the injection of the toxin alone. Two components can be demonstrated, a hemolysin (tetanolysin) and a toxin selective for nervous

tissue, especially motor cells (tetanospasmin). Local sepsis by the organism may be negligible or not even appreciable; it is noninvasive. Although a strong affinity exists between the toxin and nerve tissue, recovery is attended by no apparent nerve impairment. There probably also exists an affinity between the toxin and muscular tissue or the myoneural junctions. Antitoxin completely neutralizes free toxin, but has no effect on that already fixed by the nervous system.

Source. *Cl. tetani* is a common inhabitant of the intestinal tract of horses, cattle, sheep and fowls, and is found in soil, being especially abundant in that fertilized by manure. Human (intestinal) carriers constitute a fair proportion of the community. Spores may survive for many years in the tissues. Wound infection is prone to occur in those engaged in agricultural pursuits and in soldiers, although no group of persons entirely escapes the disease.

Pattern of infection. *Cl. tetani* is commonly saprophytic, and it is virtually impossible to infect healthy tissue with the spores. Under certain conditions, however, the organism becomes fatally pathogenic, solely by virtue of its toxin. Wound factors necessary to pathogenicity include the following: devitalized tissue, foreign bodies, especially dirt or the coexistence of infection by other organisms, and a reduced oxygen tension locally. Any wound in which any or all of these conditions exist is a potential source of tetanus. Although occurring by far the most frequently in war wounds and in those of people who work in the soil or about domesticated animals, the infection may appear in any wound, including burns, bites, powder (Fourth of July) burns, bedsores and operative wounds—more especially in the intestines and about the anus. It may be caused by non-sterile catgut used as suture material. Experience in World War I demonstrated that a wound may heal fully without the appearance of tetanus, only to develop tetanic infection following subsequent operation. In such cases the spores remain inactive because the conditions necessary for germination and growth were originally lacking, and also by reason of the prophylactic use of antitoxin. The eventual loss of the passive immunity conveyed by the latter, together with the creation of conditions favoring infection by a second operation, permits the development of the infection. For this reason reconstructive operations on wounds that may harbor the spores of this organism must be preceded by another prophylactic injection of antitoxin.

The incubation period of tetanus is usually seven to fourteen days, but the disease may appear as early as one day or after two hundred days. Under favorable conditions the organisms mul-

tiply slowly but do not become invasive and do not appear to produce an appreciable septic reaction when the infection is unmixed. They have been recovered from regional lymph nodes, but not from the blood stream. Metastatic infections do not occur. There is much evidence to substantiate the view that the toxin is absorbed by the lymphatics, through which it reaches the blood stream, and by the latter is conveyed to the central nervous system. The former belief that toxin reaches the brain and cord by way of the peripheral motor nerves is no longer regarded as tenable (Abel et al.²⁶⁻³⁰ and Firor et al.^{31, 32}).

Clinically the disease is found in two forms: local or ascending, and general or descending. In the local form, rigidity, sometimes contractions and less often spasm occur in muscles of the region of the portal of entry. These may be mild and disappear spontaneously, or may increase in intensity and extent, becoming the generalized form. In general tetanus the rigidity begins in the facial muscles and spreads slowly downward to include the musculature of the neck, trunk and extremities. Muscular rigidity progresses to spasm and then to clonic and tonic contractions, which may extend from localized groups into violent generalized convulsions. Trivial stimuli may initiate these seizures, which may become continuous, and finally death supervenes from asphyxia or exhaustion. It should be clearly recognized that at the time of the first sign of tetanus (muscular rigidity) the disease has already become established.

Management. Active immunization by toxoid to prevent tetanus bids fair to score a high mark in the present war. What few cases appear to develop following its use have a relatively low mortality. Such immunization, combined with prompt and skillful débridement of wounds and the administration of antitoxin, removes the serious menace of the disease.

Active immunization by toxoid consists in three subcutaneous injections of 1 cc. of the alum precipitate of the toxin at three-week intervals. This initial vaccination is supplemented by a stimulating dose of 1 cc. of the toxoid to those who incur wounds that might harbor the clostridium and also to those who are about to undergo secondary open or manipulative procedures and who have not within three months received toxoid.

In cases in which the patient has not received the initial vaccination and presents himself with a potentially dangerous wound, a dose of 1500 to 3000 units of antitetanus serum is injected subcutaneously to confer passive immunity. Prior to injection with serum the following sensitivity tests are carried out: Inject intracutaneously 0.1 cc. of a 1:10 solution of serum in sterile physiologic saline solution. The patient is sensitive if, after

twenty minutes, the wheal has enlarged to the size of a nickel and is surrounded by a reddened area. Next, instill in the lower conjunctival sac 1 drop of a 1:10 dilution of serum in sterile physiologic saline solution. The test is positive if, within twenty minutes, the eye is reddened and swollen. In addition to injection for passive immunity, the patient should be given the regular course of initial vaccination.

The problem of the management of established tetanus is one of protection of the patient against all stimuli possible, control of spasm by deep sedation, stopping the production of toxin by the wound, ridding the blood stream of free toxin, maintenance of general strength by adequate caloric intake and fluid balance and measures to prevent suffocation. To these ends the following measures have the stamp of approval of those^{2,3} who have given this disease the most study. The patient is secluded in a quiet, darkened room. Sedation is worked out according to the patient's best individual response. It may consist in the administration of paraldehyde by rectum, 8 to 40 cc., repeated every four hours, of chloral hydrate by rectum or orally, 1 to 3 gm., repeated every four hours, or of Avertin by rectum, 0.03 to 0.06 gm. ($\frac{1}{2}$ to 1 gr.) per kilogram of body weight. If cessation of breathing is impending, artificial respiration is mandatory; for this the Drinker respirator is best. Asphyxia from laryngeal spasm demands tracheotomy. The administration of antitoxin is delayed only long enough to test the patient for serum sensitivity (if the test is positive, desensitization is obligatory). One hundred thousand units of the antitoxin is given on the first day, as follows: 5000 to 10,000 units by infiltration about the wound, 60,000 units intravenously, and 30,000 units intramuscularly. On each of the subsequent days 5000 units is given intravenously until the attacks abate. Intravenous administration must be very slow. If the anaphylactic reaction appears, the needle is at once withdrawn and 1-cc. doses of 1:1000 adrenalin are repeatedly injected into the muscle until the symptoms of shock have stopped. About an hour after the infiltration of antitoxin around the wound, excision of the portal of entry is carried out if feasible. If this is not possible, thorough débridement is substituted. A fluid diet of 2000 to 4000 calories, preferably by a nasal tube, and a fluid intake of at least 3000 cc. are necessary to maintain the general condition.

Preferential Anaerobic Streptococci

The bacteriologic status of this group has not been clearly defined. Culturally these organisms exhibit a strong anaerobic tendency but not strictly so; they are found in both hemolytic and nonhemolytic forms. They are highly pathogenic under

special conditions, which are somewhat indefinite. Such streptococci may be recovered in pure culture from chronic undermining ulcerations (Melnick²⁴) that develop in the subcutaneous tissue, either in a traumatic wound or in one created surgically to drain an infected lymph node or for some procedure upon the intestinal or genitourinary tract. It is believed that the organism is an aerobic streptococcus altered by residence in the intestinal tract or in a lymph node. It may also produce gangrenous infection of the skin in synergistic association with *Staph. aureus*.

Identification. This is by anaerobic culture, but the organisms from some lesions may be grown aerobically.

Pattern of infection. In chronic undermining ulcers, the infection is confined to the cellular connective tissues, fat and fascia, which it liquefies. Spread is slow but persistent, undermining but not infecting the skin over a wide area and burrowing along the deep intermuscular septums. Erosion of large vessels or amyloid changes may cause death after months or even years unless the patient finally gets the upper hand or the organism is eradicated by treatment. Toxic manifestations include prostration, wasting and daily rises in temperature to 103°F.

In bacterial synergistic gangrene of the skin, the lesion is confined to the skin and arises at the margins of operative abdominal and chest wounds created for the drainage of peritoneal, pleural or lung abscess. It develops slowly—during the first week or two following operation—as an edematous, exquisitely tender area of erythema. In a few days the central portion takes on a purplish hue, which slowly spreads as the area of erythema advances and there then develops frank gangrene in the portion where the purplish area first appeared. This results in a skin lesion that is gangrenous centrally and erythematous peripherally, with a purplish intermediate zone. On the central side the purplish band is sharply defined and crenated, whereas on the peripheral side it gradually blends into the reddened zone. The involved area is raised above the surrounding healthy skin. Liquefaction of the gangrenous area takes place centrally as the infection spreads. Anaerobic culture of the tissue in the reddened zone reveals the presence of these preferential anaerobes alone, whereas the tissues in this zone are hyperemic. In the gangrenous zone *Staph. aureus* is found in association with this streptococcus. The purplish zone is edematous and is the seat of dense cellular infiltration. The two organisms are believed to produce the lesion by synergistic action, since neither alone can reproduce the infection experimentally but do so when combined. The source

of the streptococci is believed to be the intestinal tract and the staphylococcus comes from the skin or is an air-borne contaminant (Meleney³⁶).

Management. In chronic undermining ulcers, the deeper ramifications and sinus tracts resulting from burrowing are laid open widely so as to make readily accessible every recess throughout the system of infected tissue. Otherwise treatment will not be successful. Meleney's zinc peroxide dressing has usually been successful provided the suspension has access to every part of the wound. Oral sulfonamide therapy is a valuable adjunct. Hurwitz and Prien³⁵ were able to clear up this infection with locally applied sulfonamide after failing with zinc peroxide. When the infection has been eradicated, skin grafting may be necessary to cover wide, denuded areas. Where burrowing has occurred, vigilance is required to prevent fatal hemorrhage from spontaneous rupture of a major vessel weakened by erosion. Every effort should be made to maintain optimal nutrition.

In synergistic gangrene of the skin, excision of the entire focus, including a zone of healthy skin, eliminates the infection. Zinc peroxide dressings are applied to prevent recurrence. Skin grafting is necessary later to cover the defect.

Anaerobic Nonhemolytic Streptococci

Morphologically, the anaerobic nonhemolytic streptococci are similar to other streptococci; culturally they are strictly anaerobic and produce gas and a putrid odor, but not hemolysis. There seem to exist a large number of strains. Adequate classification does not exist, from which it may be inferred that our knowledge of these organisms is less complete than that of the aerobic groups.

Source. These organisms are normal inhabitants of the mouth and upper respiratory, gastrointestinal and female genitourinary tracts, but may be present on the skin and clothing as contaminants. From any of these sources they may enter wounds by inoculation.

Pattern of infection. Normally harmless saprophytes, these organisms may uncommonly become highly virulent. The condition at least partly possible for this change in behavior is the low oxygen tension found in necrotic tissue or in that created by trauma or a diminished blood supply. In some anaerobic streptococcus infections, it is found in pure culture; in others, believed to be a definite factor in the other organisms being *Staph. aureus* and *Staph. pyogenes*. The infection is putrid. It may follow the production of a condition indistin-

guishable from gas gangrene, or the aerobic streptococcus form, with rapidly spreading cellulitis and severe toxemia and, like the latter, possibly followed by intravascular sepsis, septic embolism, infarction, bacteremia, cardiac valvulitis and metastasis, including that of the bone, or a symbiotic form found in cases of human bite and characterized by intense edema, gas formation and putrid discharge. Each of these conditions is grave, or at least serious.

Management. These infections are best dealt with by excision, amputation or débridement, depending on the region involved. The resulting wound should be treated by the zinc peroxide technic. Sulfonamide therapy may be tried. Anaerobic nonhemolytic streptococcus antiserums have not been developed. For a complete résumé and bibliography the reader is referred to Sandusky, Pulaski, Johnson and Meleney.³⁷

Bacteroides and Fusiform Bacilli

The bacteroides and fusiform bacilli comprise a large group of pathogenic, gram-negative, anaerobic bacilli that are non-spore-forming. About them relatively little is known. They are frequently found in fresh wounds together with the common pathogens (Pulaski, Meleney and Spaeth³⁸). The designations refer to shape, the bacteroides having round ends, and the fusiform bacilli pointed ends. Their role as infectious agents may be confined to an intense local necrotizing action attributed to a powerful endotoxin.

TREATMENT OF WOUNDS

The seven cardinal principles that constitute the modern treatment of wounds rest on the basis of natural resistance to bacterial infection and the innate capacity of tissue to repair. These are as follows:

- A minimal time between the infliction of the wound and the institution of definitive treatment.
- The control of shock.
- The excision of devitalized and necrotic tissue and the removal of foreign bodies.
- Drainage by exteriorization.
- Rest by immobilization.
- The maintenance of a normal nutritional state.
- Immunotherapy and chemotherapy.

Time Factor

Given similar conditions, the aftereffects of a wound are directly proportional to the time interval between infliction and the coming into active play of all the various measures directed to combating the trauma. Prompt first aid, including the control of hemorrhage, emergency splinting, morphine sedation and plasma transfusion,

is effected to combat shock at its inception. The immediate oral administration of a sulfonamide drug assures its effective concentration in the blood stream at a time when it is most needed to check bacterial invasion. By efficient stretcher and ambulance organization (automobile and airplane) the excision of devitalized tissue, removal of foreign bodies and institution of adequate drainage may be carried out within a few hours or less, when these measures are extremely valuable. The early reduction of a fracture and adequate internal and external fixation are thus made possible. Intravenous chemotherapy—if the sulfonamide has not previously been given orally—and the early administration of prophylactic clostridial antitoxin may only by such prompt action avert grave infection. Prior active immunization against tetanus now seems assured.

Shock

If shock develops, in spite of all efforts to prevent it, the condition should be treated by modern accepted methods, which are outside the scope of this paper.

Débridement

Débridement by its present-day definition specifies the early and wide exposure of the entire wound, and the excision of tissue traumatized by the forces inflicting the wound and of hemorrhagic tissue. It also specifies the removal of foreign bodies and blood clot. For full realization of the benefit of this procedure as an antiseptic measure, knowledge, judgment and skill of the highest order are often necessary. Scientific investigation and clinical experience incriminate necrotic, devitalized and hemorrhagic tissue, blood clot and foreign bodies on the ground that they are culture mediums suitable for pathogenic bacteria. Conversely, healthy tissue is highly resistant to infection. In the creation of such bacteria-favoring conditions in tissue two factors predominate: local trauma and ischemia. Ischemia is present as a result of local vascular injury or of a contemporary remote injury to a major vessel supplying the injured region. Another and constant, more or less influential element in the production of ischemia is regional vascular spasm, the result of local shock and mediated by the sympathetic nervous mechanism. This produces local anoxia and edema, which may promote further ischemia by pressure. Vascular spasm has long been recognized as a factor of considerable importance in activating anaerobic bacteria—for example, those producing gas gangrene—by the creation of anoxia. Foreign bodies, such as bits of clothing, metal and dirt, are notorious and persistent contaminants that may cause a wound to remain open, draining indefinitely, and the re-

moval of which may result in prompt healing of the wound. The extirpation of these various infectious niduses is the purpose of débridement. Obviously, the earlier this is done the better. Débridement may be classified as a prophylactic antiseptic method.

The skin should be thoroughly washed with neutral soap and water over a wide area around the wound; the region is shaved if at all hairy and the soap-and-water washing is repeated. The area is rubbed with gauze saturated with benzene to remove grease and dirt, and then with gauze saturated with 70 per cent alcohol until clean. Finally it is painted with a 1 per cent iodine and 1 per cent potassium iodide alcoholic solution, care being taken that the solution does not enter the wound (Nye³⁹).

The incision should be axial and not transverse, except that in crossing the flexor aspect of a joint of an extremity the axial elements above and below are connected by a transverse element along the joint crease. It should be ample, so as to allow free visual exploration of all wound recesses. It should be placed, if possible, so as to correspond to a standard accredited approach to the depths of the region wounded and at the same time to include the center of the wound.

The jagged and necrotic skin margins of the wound are excised for a distance of 3 to 6 mm. Skin is resistant tissue with a good blood supply and should not be ruthlessly sacrificed. In cases in which avulsion of the skin has occurred, however, Farmer⁴⁰ has shown that nothing short of complete excision of the avulsed portion, removal of every vestige of subcutaneous fat and reapplication of this skin as a free full-thickness graft will alone suffice to save it. This has been repeatedly confirmed.

Fat is nonresistant and has a poor blood supply, and when at all devitalized favors bacterial activity. It is a pernicious obstacle to vascularization. When under the slightest suspicion it should be widely excised. The fasciae and septums require close scrutiny for small hematomas and traumatized portions easy to miss. Cleansing with physiologic saline solution will brighten fascia, giving it a fresh appearance, and will disclose fraying, dirt and other small foreign bodies and hematomas that might otherwise be overlooked. Such tissue is especially favorable to hemolytic streptococci and should be widely excised.

Severely traumatized and hemorrhagic muscle cannot survive and is destined to provide a virtually ideal bacterial pabulum. It may be recognized by its discoloration, by loss or impairment of contractility on pinching and (the most reliable test) by diminished bleeding—that is, absent or lessened oozing—on section. All such muscle

must be excised (by scissors) well into the normal tissue.

All but grossly necrotic portions of tendon should be spared. Damaged sheaths must be excised. Divided tendons should be sutured, if possible, using fine tantalum wire.

Both vessels and nerves are resistant to infection if conditions are at all favorable. For this reason and because of their function, they should be carefully preserved. Damaged arteries should be ligated. Severed nerves should be sutured, if possible with fine stainless steel or tantalum wire or else with fine silk.

Considerable nicety of judgment is required in the removal of bone fragments in a compound comminuted fracture. Pieces of small size (5 mm. or less) devoid of periosteum or other source of blood supply should unquestionably be removed as noxious foreign bodies. Larger fragments, undoubtedly dead, may or may not be rightly removed. Such fragments apposed to normal bone and fixed to it absolutely may serve as massive grafts that are quickly replaced by living bone, and play an important favoring role in the bone-healing process. Large defects at the site of fracture are, no doubt, advantageous from the standpoint of avoiding bone infection, but they exact a terrible toll in terms of time, loss of function and nonunion. Furthermore, before removing sizable fragments the surgeon may well recall that a fractured bone is a decompressed one and need not necessarily become badly infected. On the contrary, absolute fixation by plate or screw may be expected to protect the bone from serious infection, because it is motion at the site of fracture and not internal pressure that fosters infection of bone in these cases. One may well bear in mind, too, that osteomyelitis caused by local contamination in compound fractures, at least in civilian practice, does not imply the low resistance to specific infection found in the hematogenous form. Aside from the problem of removal of fragments, bone débridement is characterized by the care exercised to conserve periosteum and blood supply.

In the methodical layer-by-layer débridement of a wound, hemostasis must be almost absolute. Fine clamps are used to minimize tissue crushing, and ligatures of cotton, silk and fine catgut are used in that order of preference. If possible, instruments are changed with each layer.

On the completion of the excision the entire wound is irrigated from within outward with large quantities of sterile saline.

The above description applies to emergency or prophylactic débridement. Therapeutic or delayed débridement is practiced according to the same principles, except that the barrier raised by the local tissue in the inflammatory fixation must

not be crossed. It thus becomes a procedure of excision of necrotic tissue that would otherwise have to be sloughed off, the removal of clot and foreign bodies and the exteriorization of undrained recesses.

It is of the first importance to culture excised tissue and exudate aerobically and anaerobically in order that accurate knowledge of the pathogenic flora may be gained from the outset. In this way subsequent management may be effectively conducted.

Drainage

Clean incised wounds, débrided early in robust patients in civilian practice, may be closed without drainage provided close follow-up and complete postoperative immobilization are possible. Such wounds may be expected to heal by first intention in a considerable proportion of cases. On the other hand, freedom from infection in extensive lacerated contused and dirty wounds and in all war wounds is not to be expected. However, early complete healing of such wounds by secondary intention should be provided for by adequate drainage. Transverse incisions of the aponeurosis are therefore made to decompress the wound and anticipate subsequent edema. The entire wound is then packed loosely with gauze saturated with boric acid ointment or vaseline to hold apart gently the walls of the wound. Such packing does not impede the clearance of discharge, irritate the tissue, or in any way promote anaerobic infection. The wound is protected against subsequent contamination by an ample dressing and the region is immobilized by appropriate external fixation.

Immobilization

The broad principle involved in immobilization is the curative effect of rest. A number of factors combine to this end. These may be divided into three groups: the control of pain, the control of absorption and the control of subsequent trauma.

Immobilization of the injured part reduces the painful afferent nerve stimuli arising out of the wound itself. These are caused by motion in the injured region, by muscle spasm and by pressure from edema. General shock is thus markedly lessened and local muscle, and sympathetic vascular spasm can subside and disappear. There results in turn subsidence of edema, with the result that there is further lessening of the pain factor.

Experimental evidence indicates that the absorption of toxic substances resulting from tissue damage, of bacterial toxins and of bacteria themselves takes place largely through the lymphatics, and it has been demonstrated that the rate of lymph flow is greatly reduced by immobilization, not only physiologically but in the presence of

edema and inflammation (Drinker and Yoffey⁴⁰ and Barnes and Trueta⁴¹). It is well known, furthermore, that toxins that are lethal in massive dose may be neutralized and eliminated without demonstrable ill effect if their rate of introduction to the blood stream is relatively slow. Clinical experience has repeatedly demonstrated the minimizing effect caused by immobilization on many toxemias.

Splinting favors wound repair by protecting new tissue capillaries from abnormal tension, twisting and bending, that is, from the repeated subsequent minor traumas caused by motion. These retard healing, lead to dense avascular scar tissue and cause mechanical spread of infection.

Nutrition

The influence of diet on wound healing has been discussed thoroughly in a previous progress report (Holmes⁴²). In general, the optimum diet for patients with infected wounds is one of high-calory, high-polyvitamin content, and this is so selected that the protein fraction is raised at the expense of the fat. Whereas the role of vitamin C deficiency in arresting the formation of intercellular substance (collagen and osseomucin) has been clearly defined, that of vitamins A and D in wound healing and in resistance to infection has not. There is in surgical infections an excessive demand for vitamins that quickly depletes the reserve supplies unless these are maintained either by diet or by direct administration. Increased attention is being paid to the part played by blood protein in tissue repair and resistance to infection and in combating the toxemia resulting from infected wounds. All the evidence points to the importance of this factor. Infection with toxemia causes a drop in the production of plasma protein, and conversely hypoproteinemia lowers resistance to infection, retards tissue repair, lowers general body tone and causes edema. The control of the protein reserve balance in the plasma and tissues in cases of wound infection has not yet been effected. Protein ingestion by mouth has so far proved to have the best effect. Repeated whole-blood and plasma transfusions have not been especially effective in raising the protein level of the blood.

Immunotherapy and Chemotherapy

The various applications of immune serums and the use of toxoid have already been discussed under management of the different infections.

The bacteriostatic property of the sulfonamides when given orally or intravenously is so clearly and widely appreciated that no further comment is required here. The local application of these drugs to fresh wounds combined with oral administration is still a somewhat controversial point,

and scientific evaluation is still lacking. One may detect a tendency away from their topical use on the clinical ground that most wounds do as well or better without as with these drugs, and on experimental grounds because of their being prone to act as foreign bodies when not dissolved, because of their toxic effect on tissue cells in high concentration, because of their inability to penetrate devitalized or necrotic tissue, and because their bacteriostatic action is inhibited by wound exudate. On the basis of physical properties—greatest solubility in serum, greatest wound diffusion, most rapid clearance from the wound and quickest excretion—sulfanilamide seems best adapted to this use. The crystals should be evenly sprinkled over the surfaces of the wound in an amount not to exceed 0.1 gm. per square inch of wound surface. For a critical review, the reader is referred to Lyons and Burbank.⁴³

I am indebted to Dr. Champ Lyons for help in the selection of sources.

EDITH E. PARRIS, *Assistant Editor*

CASE 29301

PRESENTATION OF CASE

A fifty-five-year-old widow entered the hospital because of painless jaundice of two weeks' duration.

The patient had been in good health until three months before entry when she began to experience a feeling of pressure in the epigastrium coming on usually about two hours after lunch and lasting well into the evening. At times she felt nauseated; she very rarely vomited, and when she did the vomitus consisted of slightly sour, undigested, recently eaten food. The patient gradually developed an almost complete aversion to food and ate only small amounts of fat-free food; often she ate only toast for dinner. Four weeks prior to admission she noticed that the urine was dark brown, and the stools pale. She soon became jaundiced and the skin began to itch. The jaundice deepened, and the abnormal colored urine and stools persisted to the time of admission. During the illness her bowels remained regular, and only occasionally did she require Epsom salts for the relief of mild constipation. She had lost 10 pounds in weight during the previous three months. She believed that recently the abdomen and ankles had begun to swell.

The patient's mother died at fifty-five years of age with carcinoma of the breast. Two sisters had had hysterectomies done because of menorrhagia. Four years prior to admission the patient was sterilized by x-rays, because of persistent metrorrhagia; she had no further bleeding but continued to have a vaginal discharge and occasional pain in the right lower quadrant of the abdomen. Two years prior to admission the uterus, tubes and ovaries were removed for "fibroids."

Physical examination disclosed a thin, deeply jaundiced woman who appeared restless. The scleras were deeply jaundiced. There were many excoriations about the trunk, numerous small (1 to 2 mm.) purpuric spots about the knees and small "spider angiomas" of the arms, face, neck and thorax. The lungs and heart were normal.

The liver edge was felt three fingerbreadths below the costal margin in the epigastrium. A mass that descended to the umbilicus on inspiration was believed to be an enlarged gall bladder. No tenderness was elicited. There was slight pitting edema at the ankles.

The blood pressure was 90 systolic, 55 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a hemoglobin of 10.9 gm. per 100 cc. and a white-cell count of 9600. The urine was acid, had a specific gravity of 1.020 and showed a + test for albumin and a +++ test for bile; the sediment contained amorphous urates and 6 white cells and 6 epithelial cells per high-power field. A blood Hinton test was negative. The prothrombin time was normal. The total protein was 5.0 gm. per 100 cc., and the bilirubin 12.3 mg. direct and 17.5 mg. indirect. The stool was light brown in color and guaiac negative in four examinations. The sedimentation rate was 16, 32, 44 and 49 mm. in fifteen, thirty, forty-five and sixty minutes respectively. A gastrointestinal series demonstrated a normal stomach and esophagus. The duodenal cap was large, and the tip was narrowed, apparently by an extrinsic band or blood vessel crossing it. The second portion of the duodenum showed no constant defects or evidence of rigidity of the wall.

After two weeks of preoperative preparation, including administration of water-soluble vitamin K and glucose-saline infusions, an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. AUSTIN BRUES: This appears to be a classic case of carcinoma of the head of the pancreas. I shall therefore discuss it from the point of view of seeing whether any other diagnosis will fit with the history as given.

The age of the patient is consistent with that diagnosis, the average age in most series being the late fifties. The prodromal gastrointestinal symptoms without pain and with anorexia and weight loss are common, weight loss being extremely marked in certain cases of carcinoma of the head of the pancreas. At the time the symptoms appeared the patient had progressive jaundice, which became intense, with itching. The enlarged liver and the enlarged gall bladder, according to Courvoisier's law, indicate a constantly progressive lesion low down in the biliary system. The patient had a high bilirubin, direct and indirect, an elevated sedimentation rate and a normal prothrombin time. One might expect the prothrombin time to be elevated in jaundice; however, if the lesion produced obstruction primarily, the liver might

*On leave of absence.

have been able to maintain a normal blood prothrombin level for a period of some weeks.

I should say that the chief observation not in line with this diagnosis is that of spider angiomas, which are seen characteristically in cirrhosis of the liver, and may be observed a long time before the cirrhosis becomes manifest in other ways. They also have an endocrinologic angle, since they may appear during pregnancy and may be increased, when already present in patients with hepatic cirrhosis, by the administration of estrogen. It has been suggested that spider angiomas represent loss of liver function. Since the cirrhotic liver is unable to destroy or metabolize estrogen, this vicarious endometrial manifestation occurs in the skin. It is worth remarking incidentally that this woman was sterilized first by x-rays and then by ovariectomy. In line with the theory mentioned, it might be supposed that the angiomas antedated these procedures. At any rate, they suggest, but by no means prove, that the liver may have suffered chronic low-grade damage or was cirrhotic.

Another observation not quite in line with the diagnosis is that the stools were light brown. The obstruction therefore was not complete. That may have been an erroneous judgment; such things can occur. The obstruction may not have been incomplete, although anatomic considerations make it likely that once carcinoma of the head of the pancreas gives obstruction it shortly becomes complete, and that is what usually happens, unless there are anomalous or accessory bile ducts.

The low plasma protein and ankle edema may have been due to faulty nutrition; along with spider angiomas they might suggest a long-standing, low-grade hepatic insufficiency, but there is nothing else to indicate it. The prothrombin time was normal, and I am merely going to make the suggestion that there might have been some chronic liver damage unrelated to the main lesion. The slight albuminuria is consistent with jaundice.

Among the other diagnostic possibilities worth suggesting, the first is something associated with a low-grade chronic cirrhosis that would give these manifestations. The best of these probably is hepatoma. In that case the mass thought to have been gall bladder would be the tumor. The jaundice would be due to intrahepatic obstruction, and this would account for the small amount of bile in the stool. On the whole I think that is improbable. Carcinoma of the gall bladder might be considered. In that case the mass would be the carcinoma and again the obstruction would be intrahepatic from metastases high in the biliary system. Furthermore, I cannot rule out obstruction from some uncommon cause, such as fibrosis of the pancreas, lymphoma or metastases to peripor-

tal nodes compressing the bile duct. The fact that there was no palpable spleen is against lymphoma. I am against common-duct stone: Courvoisier's law is against it, as is the absence of pain and the steadily progressive nature of the jaundice. A common-duct stone can occur in a small percentage of cases without one of these anomalous findings, but from the laws of probability it seems extremely unlikely that these three unusual features could occur together. Carcinoma of the ampulla or of the duodenum I disfavor because of the absence of blood in the stool. My final diagnosis is carcinoma of the head of the pancreas.

DR. CHESTER M. JONES: It seems to me that it is entirely probable that this woman had cirrhosis. Only a rare case with spider angiomas fails to have cirrhosis, excluding those cases observed in pregnant women. I think that this woman had severe liver damage. We do not know what the serum albumin was. The liver was certainly enlarged, and ankle edema and ascites were present. The fact that the patient had brown stools makes it conceivable that the whole clinical picture was due to intrahepatic disease alone. We have had cases of acute hepatic insufficiency with brown stools, a palpable liver, abdominal pain and fever. The important thing is that a definite diagnosis was not possible and therefore that exploration was indicated. I believe that carcinoma of the pancreas is less likely as a diagnosis than acute hepatic insufficiency or chronic liver disease with superimposed hepatoma.

DR. BENJAMIN CASTLEMAN: You are basing all your conclusions on the spider angiomas?

DR. JONES: Not entirely, but they furnish important evidence. The facts that there was color in the stool and that the patient had ascites and edema cannot be overlooked.

DR. ARTHUR W. ALLEN: I should like to add that, for some reason or other, the types of obstructive jaundice that give brown stools or intermittently brown stools are much more apt to be associated with malignant disease than with any other type of biliary obstruction. I do not know why. Frequently a little bile goes through in cases of carcinoma, particularly of the papilla.

DR. CASTLEMAN: Possibly that can be explained by the fact that the carcinoma often becomes necrotic, sloughs off and thus partially relieves the obstruction. It is seen more commonly in carcinoma of the papilla than in carcinoma of the head of the pancreas because the necrotic tumor may slough into the duodenum.

DR. GREENE FITZHUGH: This patient was operated on because her jaundice increased. We considered peritoneoscopy, but the jaundice increased

so rapidly that we thought it wiser to go ahead and do something about it.

DR. JONES: As I have said, the important thing here was to make the decision and not the diagnosis. But, in a case of this sort, one has to be prepared for liver disease as well as something outside the liver.

DR. RICHARD H. WALLACE: At operation the mass was a greatly distended gall bladder. The common duct was about 3 cm. in diameter. A mass was felt in the head of the pancreas. Fortunately we could make a diagnosis very readily because the tumor had extended through into the duodenum, or perhaps it started there, there being an area about 3 cm. in diameter with a central crater in the region of the papilla of Vater. We were able to resect the head of the pancreas with the proximal two thirds of the duodenum, and fortunately we could deliver the end of the duodenum beneath the mesenteric vessels and suture it to the end of the dilated common duct and were conveniently able to anastomose the end of the stomach to the side of the jejunum, making only two anastomoses. The patient had a smooth convalescence and is well today so far as we know.

DR. BRUES: Did you observe *typical* spider angiomas?

DR. WALLACE: She had what I consider to be spider angiomas.

DR. JONES: The pulsating sort?

DR. WALLACE: I am not sure of that.

DR. CASTLEMAN: How did the liver look?

DR. WALLACE: It was the enlarged, greenish liver that one sees with obstructive jaundice.

CLINICAL DIAGNOSIS

Carcinoma of head of pancreas.

DR. BRUES'S DIAGNOSIS

Carcinoma of head of pancreas.

ANATOMICAL DIAGNOSES

Adenocarcinoma of duodenum, involving the papilla of Vater, with extension to the pancreas and with metastases to the regional lymph nodes.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: We received a section of duodenum, 10 cm. long, with the attached head of the pancreas. On the mucosa of the duodenum surrounding the papilla of Vater was a large ulcerating tumor 3 cm. in diameter, with raised borders and a central ulceration. In the center of the crater was the opening of the common bile duct, which was markedly narrowed. The bile duct

above the constriction was dilated. This tumor proved to be an adenocarcinoma that had extended through the duodenal wall to involve the surface and a very small portion of the pancreas. There is no doubt in my mind that the tumor was primary in the duodenum rather than in the pancreas. The regional lymph nodes were enlarged and hard and were filled with metastatic carcinoma. These were close to the head of the pancreas and were probably what was believed to have been the mass within the pancreas at operation.

CASE 29302

PRESENTATION OF CASE

A forty-four-year-old single woman entered the hospital because of profuse menstrual bleeding of a year's duration.

Menarche occurred at eleven years, and prior to the present illness, periods occurred regularly, with a twenty-eight-day cycle, and lasted five days. During menstruation the flow was moderate, requiring two napkins a day. On the fourth or fifth day she often had mild abdominal cramps. Approximately one year prior to admission the patient noticed gradual increase in the amount and duration of menstrual bleeding. About four months before entry her periods began to occur every twenty-four or twenty-five days and each lasted eighteen to twenty-one days. During the first two weeks she frequently passed small and moderate-sized blood clots. During the year of illness she suffered with a "bearing down" sensation in the pelvis but there were no changes in bowel or urinary habits and no weight loss. The last menstrual period began thirteen days prior to admission and flow continued to the day of admission.

The family and past histories were noncontributory. During the week prior to admission she had had an upper respiratory infection, from which she had recovered without sequelae.

Physical examination disclosed a well-developed and well-nourished woman who seemed quite comfortable. The pharynx was slightly congested, and the tonsils slightly enlarged. There was a soft, blowing systolic murmur audible over the entire precordium, best heard in the mitral area. The lungs were normal. A firm, slightly tender, irregular mass was felt in the lower abdomen. Vaginal examination under ether disclosed a normal-appearing cervix and a small vagina. The uterus was large but freely movable, and the vaults were negative.

The blood pressure was 125 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

The blood was normal. The urine was bloody. A blood Hinton test was negative.

An operation was performed on the second hospital day.

DIFFERENTIAL DIAGNOSIS

DR. JOHN ROCK: It is important throughout the history to note the terminology used in reference to the bleeding. It was profuse menstrual bleeding, which does not indicate what is commonly called "metrorrhagia." There is no suggestion of intermenstrual bleeding. The description makes me believe that this was polyhypermenorrhea and not dysfunctional flow or metrorrhagia.

"During the first two weeks she frequently passed small and moderate-sized blood clots." There was therefore some derangement of menstruation.

We are not told how large the abdominal mass was or where it was located in the abdomen, except that it was in the lower abdomen. It may have been on one side or the other, or very large or only palpable just above the symphysis. The fact that the vagina was small suggests that the vagina might have been encroached upon. The patient was unmarried; perhaps the vagina was normally small. We are told that the uterus was large, but we do not know how large—perhaps 6 or 7 cm. wide and 4 or 5 cm. thick or it might have reached up to the umbilicus. There was a mass in the abdomen, which may have been the uterus, but nothing was felt in either vault.

There was no blood dyscrasia to account for the polyhypermenorrhea. The urine was bloody, but if it was a voided specimen one would expect it to be bloody because the patient was flowing when she came in.

As I have said, we have to account for polyhypermenorrhea occurring in a forty-four-year-old woman that was associated with a mass in the lower abdomen and an enlarged uterus. Polyhypermenorrhea, that is, periods occurring at intervals shorter than the classic twenty-eight days, is not uncommon in a woman forty-four years old. Even excessive flow is not uncommon, but such marked prolongation of the periods indicates some pathology. So we might consider that it probably was due to whatever made the mass in the lower abdomen and enlarged the uterus. Following Cabot's instruction to make one diagnosis cover as many situations as possible, we had better say that the mass in the abdomen was the enlarged uterus. One can account for the bleeding perhaps by polyps, which prolong flow and result in the formation of clots. But polyps usually do not enlarge the uterus. Fibroids are of course the first thought that one would have to consider to ac-

count for all these things, probably multiple fibroids, because the mass in the lower abdomen was irregular. The patient could have had sarcoma, with or without fibroids, or she could have had endometriosis of the uterus itself. Endometriosis of the uterus is not uncommon and it does cause enlargement, which may be irregular; it usually does not cause intermenstrual flowing but increases in the amount and prolongation of the flow. It may also give enlargement of the uterus that is sufficient to be felt above the symphysis.

Then of course there is cancer. I think it is impossible to make a particular diagnosis here. Cancer in a forty-four-year-old woman sufficient to cause enlargement of the uterus and mass in the lower abdomen would have certainly given more bleeding than this patient had, and a different kind of bleeding.

We have to assume that the tumor was the uterus and that the ether examination was accurate. It is easy to mistake a tumor of either ovary for one of the uterus, and often an operation for fibroids is performed, because statistically they are the commonest cause of enlargement of the uterus, only to find that the tumor is a contiguous one of the ovary and not an outgrowth from the uterus.

Because the bleeding was of the menstrual variety we have to limit the diagnosis to fibroids or endometriosis of the uterus. How can we distinguish between these two? I do not know. Fibroids commonly give no symptoms whatever. They are troublesome only because of their size.

I think one was bound to operate on this patient with a working diagnosis of fibroids of the uterus but with the possibility of finding endometriosis or possibly sarcoma.

DR. JOE V. MEIGS: I think it is only fair to tell Dr. Rock that the patient did have a mass on one side.

DR. ROCK: If the mass on one side could be considered a tumor of the ovary then we must consider a tumor that does not interfere with ovulation. I do not know any tumor of the ovary that gives enough estrogen to increase flow without interfering with ovulation. But if the uterus is really enlarged in a woman of forty-four, we must assume some extra stimulation in the uterus, and therefore this patient might have had a granulosa-cell tumor of the ovary or, again, endometriosis of both the ovary and the uterus.

DR. MEIGS: I think the diagnoses that we made before we operated on the patient were fibroids and endometriosis. We knew there was a mass on the right side, which Dr. Rock did not know. I did not curet her because I was going to do a total removal of the uterus anyway.

At operation I found a cystic lobulated mass the size of an orange in the right ovary. One of the cysts had ruptured and there was a moderate amount of clear, free fluid in the abdomen. The whole uterus and the right ovary and tube were removed. My habit is to open the uterus before closing the abdominal wall, but this one time I did not do it. We had the patient's abdomen partially closed, when I realized I had not looked at the ovary or uterus. I stopped and opened the ovary, and much to my surprise, there were papillary areas and soft tissue inside. When I opened the uterus I found similar soft granular tissue on the endometrium, which made me think that the tumor had metastasized to the right ovary. I reopened the wound and removed the other tube and ovary.

The patient also had fibroids of the uterus and endometriosis of the pelvis.

CLINICAL DIAGNOSES

Fibroid of uterus.
Endometriosis.

DR. ROCK'S DIAGNOSIS

Uterine fibroid?
Endometriosis?

ANATOMICAL DIAGNOSES

Adenoacanthoma of uterus, with metastasis to right ovary.
Leiomyomas of uterus.
Endometriosis of uterosacral ligament.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: We received three separate specimens. First the right ovary and tube and uterus, then the other ovary and tube and finally a small piece of tissue that had been removed from the pelvic floor.

DR. MEIGS: The left uterosacral ligament.

DR. CASTLEMAN: The ovary was cystic, as Dr. Meigs has said, but the tissue inside was not really

papillary. There was a mass of soft, friable tumor, which on section proved to be exactly the same as the tumor in the fundus of the uterus, an adenoacanthoma, that is, parts of tumor were adenocarcinomatous and other parts showed squamocell change or epidermoid carcinoma. This type of tumor is quite common in the body of the uterus, and I believe has a poorer prognosis than the straight adenocarcinoma.

DR. MEIGS: I should not say that. If it is treated with radiation, the outlook is poor, but if treated with surgery the results are fairly good.

DR. CASTLEMAN: Just about the same as those in adenocarcinoma?

DR. MEIGS: Yes.

DR. CASTLEMAN: If one finds a tumor in the ovary and one in the uterus it is often difficult to tell which is primary. The fact that this tumor was an adenoacanthoma proves that it was primary in the uterus. I do not believe that we have ever seen a primary adenoacanthoma of the ovary.

DR. MEIGS: Dr. Richard H. Miller had a case of primary adenoacanthoma of the ovary here years ago; nothing was found in the endometrium.

DR. CASTLEMAN: The uterus also contained large fibroids, and the small piece of tissue removed from the uterosacral ligament showed endometriosis. So the patient had all three diseases.

DR. MEIGS: The tumor in the uterus was not localized to one area but filled the entire endometrial cavity. This made me think that the metastasis was from the endometrium to the ovary and not from the ovary to the endometrium.

DR. CASTLEMAN: Why did you not do a curettage first, Dr. Meigs?

DR. MEIGS: If I am going to remove the entire uterus, I do not believe it is necessary; furthermore, if cancer is present a curettage may still tumor. The uterus, however, must be opened before closing the abdominal incision.

DR. CASTLEMAN: I have never been convinced that a curettage will implant tumor lower down. If metastases do occur in the vagina, I believe that they get there via the lymphatics.

AWARD TO DOCTOR JOSLIN

To have been awarded the Distinguished Service Medal and Award of the American Medical Association and thus to be placed in the group of outstanding physicians that includes Hektoen, Herrick and Chevalier Jackson is an honor of which any man may justly be proud, and we of New England may similarly be proud that the recipient is Dr. Elliott P. Joslin.

A simple man of tireless energy and boundless enthusiasm, he has devoted his life to the treatment of diabetes mellitus. He has systematically trained the patient in knowledge of the disease so that life may be prolonged and health preserved. He could

not have become such an outstanding specialist had he not had extensive general clinical experience abroad and later on the wards of the Boston City Hospital. He could never have acquired such detailed knowledge of diabetes had he not possessed infinite patience and been endowed with the ability to prevail against seemingly hopeless odds. His success would have been far less had he not recognized unconsciously that "the secret of the care of the patient is caring for the patient."

We congratulate Dr. Joslin on his achievement, and we hope that he may for many years continue the work for which so many thousands give thanks.

THE SYMBOL OF BUREAUCRACY

Physicians, with few exceptions, have been well treated so far as gasoline rationing is concerned, and their privileges have usually not been abused. They have been recognized as a hard-working, essential group of men and women, with more than average social consciousness and conscience. There has always been a tendency, in fact, to idealize their position in the community, to sentimentalize a little over their devotion to duty and their appetite for hardship and to grant them indulgence, as a class, on that account.

The fact is not to be lost sight of, however, that extra gasoline is not given as a reward for merit but as a means of enabling the physician to perform his functions in the community as efficiently as possible. He is made thereby, not a pampered idol, but a trusted public servant. The very nature of his services and the unpredictability of their character make it imperative that he should have his mode of transportation at hand. If he is permitted to have his recreation,—and the most zealous bureaucrat would hardly deny it to him,—he must have his car with him, if he is to stay on call. In all other ways he is an A-card holder, subject to the same restrictive regulations, the same lack of privilege and the same penalties that the owner of a so called "pleasure car" enjoys.

The whole question of gasoline rationing merits

a serious review for here, in the minds of many who still cherish the idea of the rights of the individual, bureaucracy has committed one of its most serious blunders. It is not that gasoline rationing is unneeded; it is undoubtedly a stern necessity, recognized as such and accepted as such by the vast majority of citizens. It is the inability of bureaucracy to distinguish between the right and the wrong ways of directing a democratic people that is disquieting. To apportion the residue of gasoline that is left over after the necessities of war and the welfare of the public have been cared for is a reasonable procedure, even if the share of each person is only a gill a month. However, to set spies among the people to determine how each shall use his microscopic share, or suffer penalty, is quite different, and one of the most amazing things that has taken place on these shores since the Stamp Act engendered in the minds of a nation the idea of freedom from oppression.

It sometimes seems as if there were fixed in the collective mind of bureaucracy not only the idea that gasoline must be saved, but that in the saving thereof the people must be scourged. One can see rising in the form of a fuel director the spirit of Cotton Mather, purging the citizens of their devils and burning the witches at the stake.

MEDICAL EPONYM

WINTRICH'S PHENOMENON

This is described by M. Anton Wintrich (1812-1882) in the section "Krankheiten der Respirationsorgane [Diseases of the Organs of Respiration]," in the first section of the fifth volume of Virchow's *Handbuch der speciellen Pathologie und Therapie* (Erlangen, 1854). A portion of the translation follows:

The change in pitch of the tympanic note over superficially situated cavities, connected via the bronchi with the trachea, larynx, mouth and so forth, by a continuous column of air, is a very pretty phenomenon. If the patient closes his mouth or swallows, thus narrowing or closing the opening of the larynx by lowering the epiglottis, the tympanic note immediately becomes fainter . . . and deeper, and vice versa [when he opens his mouth].

OBITUARY

WILLIAM FESSENDEN WESSELHOEFT

1862-1943

Dr. William Fessenden Wesselhoeft died of coronary disease and arteriosclerosis on June 27, 1943, at the Massachusetts Memorial Hospitals. He was born in Boston, March 5, 1862, and graduated from Harvard College in 1884; having rowed on the freshman crew and played varsity football. After graduating from Harvard Medical School in 1887, he took postgraduate courses at the Rotunda in Dublin, and in Vienna. He was the third William Wesselhoeft in line to practice medicine in Boston.

His grandfather received his medical degree at the University of Jena in 1820. Owing to membership in the Burschenschaft League and his volunteering as field surgeon to help the Greeks in their struggle for freedom, he was forced by Prussia and Austria to take refuge in Switzerland, where, for two years, he was demonstrator of anatomy at the University of Basel. On being warned that his extradition was sought, he walked all the way to Antwerp, where he took ship for New York and settled in Siegersville, Pennsylvania, in 1824. Thus he was one of the forerunners of those many political refugees from Germany who came over in great numbers with Karl Schurz in 1848, and the many more who have followed in this past decade. Through the influence of fellow refugees, Beck and Follen, Dr. William was asked to consider a position dealing with physical education at Harvard College, but this never materialized. He became interested in homeopathy and was one of the founders of what is now the Hahnemann Medical College in Philadelphia. He moved to Boston in 1842 and, as the story goes, was refused admission to the Massachusetts Medical Society on the grounds that he failed to bleed a case of typhoid fever. His brother, Robert Wesselhoeft, likewise a physician refugee, founded the "water cure" in Brattleboro, Vermont. This was the origin of a family of physicians in New England that found in homeopathy something more to their taste than the bleeding, blistering and purging so much in vogue at that time.

William Fessenden Wesselhoeft was the son of William Palmer Wesselhoeft, a graduate of Harvard Medical School in 1857 and an ardent homeopathist of the irreconcilable, high-dilution school, with a strong personality and advanced views regarding fresh air and the value of a mixed diet. The son espoused the hygienic views of the father, but lacking any true enthusiasm for the homeopathic method he took up surgery, working his

way up through the grades to the position of surgeon at the Massachusetts Memorial Hospitals and professor of clinical surgery at Boston University School of Medicine. He introduced a new surgical knot and devised a method of sterilizing catgut that was long in use at the Massachusetts Memorial Hospitals and elsewhere.

In World War I, with the rank of lieutenant colonel and as commanding officer of Base Hospital No. 44, he took this unit to France and served with it at Pougues les Eaux. He was a member of the Boston Surgical Society and a fellow of the American College of Surgeons. He never joined the Massachusetts Medical Society, a last flicker of protest handed down from a generation that exhibited a lively hostility.

Dr. Wesselhoeft married Emily Bradley, of Boston and Brattleboro, Vermont, who died in 1931. He is survived by four daughters: Margetta, widow of the late Dr. Bigelow, formerly commissioner of health of Massachusetts and Superintendent of the Massachusetts General Hospital; Susan, wife of Mr. Renouf Russell; Alice, wife of the honorable Leverett Saltonstall, governor of Massachusetts; and Emily, wife of Colonel William A. Barron, Jr., chief-of-staff of the First Service Command. He is also survived by thirteen grandchildren, two of whom are now serving in the Marines, three in the Navy and one in the Army. There are five great grandchildren.

Besides his many relatives, Dr. Wesselhoeft leaves behind him a large number of devoted patients and a host of colleagues who, as former students and subordinates, cherish the memory of his idealism for professional honesty, his spirit of service and his sympathetic manner at the bedside.

C. W.

MISCELLANY

"THE DOCTOR'S AUTOMOBILE"

Under the above title, the following statement, signed by Dr. Emery M. Potter, president of the Providence Medical Association, appeared in the July issue of *Medical News*, the official bulletin of the association. It is such an honorable and fair appeal that further comment seems unnecessary.

In the present-day practice of medicine the doctor finds his automobile an extremely necessary and vital instrument. Consequently the publication recently of rules and regulations by the Office of Price Administration to clarify the driving permitted and prohibited under the ban on so-called "pleasure driving" has caused much comment and speculation among the profession. The question arises as to how a doctor may pursue his regular routine and at the same time have

his automobile accessible for emergencies without violating the OPA restrictions.

First let it be clearly understood that the Rhode Island OPA authorities are sympathetic with the problem which faces the doctor, and they are clearly cognizant of the fact that of all civilian groups the doctors of medicine—particularly those who are subject at all times to demands to administer to the sick, to respond to civilian disasters, to serve the Civilian Defense program, or to meet any general threat to the health of our community—have an imperative need to have their automobiles available in order to answer emergency calls promptly.

The OPA authorities here are fully aware of the shortage of doctors in the State owing to the withdrawals to meet the demands of the armed forces. Therefore they are particularly anxious to avoid the prosecution of any doctor for the violation of the rules of driving. But this desire to protect the health of the citizens and at the same time not to inconvenience the doctors of the State calls for a corresponding sincere co-operation by each physician. To date that co-operation has not been forthcoming at all times.

Several fundamental factors must be considered by the doctor as he justifies the use of his automobile for reasonable nonprofessional driving in order that he may have his car accessible for his personal use for emergency calls.

First—The doctor must realize that his professional calling places him in a preferred class, and he is obligated not to abuse the privileges accorded him. If the patient is denied the right to drive to the beach, or to drive to and from a summer home, then the doctor too must forego the same pleasures.

Second—While relaxation from strenuous work is essential for everyone, the doctor as well as the patient, the auto driving involved to reach recreational centers cannot in all fairness be more for one than for the other. Reasonable driving, even for social calls, may be undertaken by the doctor in order that he may have his automobile at hand for emergency hospital or sick calls, but the doctor must not misinterpret what constitutes reasonable driving under such circumstances.

Third—No doctor should embarrass his professional colleagues, nor should he antagonize public opinion, by flagrant violation of the OPA rules and regulations under the excuse of a physician's privilege to operate an automobile. Open violations of the restrictions certainly should merit penalty for all persons equally.

Fourth—The gasoline shortage in this area is far more critical than the average person realizes, and unless the situation eases in the next few weeks as the result of public co-operation, far more drastic restrictions, for doctors as well as for everyone else, are in the offing. No doctor should be guilty of abetting a black market under any circumstances.

Fifth—Remember we are still in an all-out war which will be won or lost by the way we fight it on the home front.

With these facts in mind you should be well guided by your conscience as you decide whether you are truly justified as a citizen aiding the war effort—not as a doctor exercising a special privilege—to use your automobile for nonprofessional driving.

CORRESPONDENCE

TAX-SUPPORTED MEDICAL CARE

To the Editor: The following letter addressed to all boards of public welfare and bureaux of old-age assistance in the State has been sent out this week. Each appointed city or town physician, and each physician who provides medical care for recipients of public assistance in any category, should obtain a copy of this formulary from the board of public welfare of the town in which he practices. The boards will greatly appreciate co-operation from physicians in the form of close adherence to the items on the formulary in their prescriptions. The boards will be able to provide physicians with any information that they may wish to obtain in regard to the formulary.

B. W. MANDELSTAM, M.D.
Medical Adviser

Department of Public Welfare
Division of Aid and Relief
State House
Boston

* * *

Gentlemen:

Administrators of public assistance have had many problems in connection with the provision of drugs for recipients of public assistance. Because of these difficulties the State Department of Public Welfare decided to compile a formulary. The formulary will be used by the department in reimbursing local boards of public welfare, but local boards will continue to deal directly with recipients, pharmacists and doctors.

The formulary has been compiled after a study of formularies of a number of hospitals, with suggestions from pharmacists as to those drugs most frequently dispensed. The list of drugs in the formulary, and the prices, have been approved respectively by the physicians' advisory committee and the druggists' advisory committee to the medical adviser of the State Department of Public Welfare.

With very few exceptions the list is composed of drugs that are standard *United States Pharmacopeia*, and not proprietary, products. Proprietary names have been listed in a number of instances, with a cross reference to the *U.S.P.* drug which is equivalent. The list has been prepared in alphabetical form for convenience. Revision will be made from time to time, depending on changes in price or on demand by physicians for additions.

The department will not reimburse local boards for drugs not on this list, unless prior approval has been obtained from the district office of the department. The price paid for any medication on the list will not be greater than the price listed therein. Every effort has been made to adjust quantities and prices so that physicians can prescribe sufficient medication to last for the whole interval between visits.

There are two types of formulary—one with prices and one without. The former is for the use of druggists who are providing medicine to recipients of public assistance. That without prices is for the use of physicians who are providing medical services to such recipients. Local boards of public welfare may secure the needed number of each type from their district office.

Where the recipient is allowed to purchase drugs from any pharmacist, or from a limited number of pharmacists, the mechanism of billing for the drugs depends on

the local board of public welfare. Arrangements should be made between the druggist and the local board for the proper method of billing the recipient or the board.

Further information will be furnished from the Department of Public Welfare through the district office.

BOOK REVIEW

Electrophoresis of Proteins and the Chemistry of Cell Surfaces. By Harold A. Abramson, Laurence S. Moyer and Manual H. Gorin. 8°, cloth, 341 pp., with 155 illustrations. New York: Reinhold Publishing Corporation, 1942. \$6.00.

This book deals with a rapidly expanding field of investigation, which is of growing importance in medical science. The fact that charged particles (including cells, bacteria and protein molecules) move in an electric field has long been appreciated, but only recently has it been put to use through the development of the Tiselius and similar instruments. With proteins, electrophoretic methods may be used to estimate the quantities of components of different mobilities in a mixture such as plasma, to separate these components and to demonstrate the identity or heterogeneity of a chemically isolated fraction.

Many clinically useful tests (albumin-globulin ratio, sedimentation rate, Takata-Ara reaction, colloidal-gold test) depend on variations in the protein pattern. Whereas plasma albumin migrates as a unit, the globulins can be separated into at least three components, so that electrophoresis has much potential clinical value. Certain antibodies are recognized by the great increase in quantity of a protein component occurring in hyperimmune sera and by its disappearance after absorption by the specific antigen. The antibody components are identical with the gamma globulin or fall between the gamma and beta globulins on the electrophoretic diagram. Consequently, the supposition has been made that the increase in plasma gamma globulin occurring in sarcoidosis and amyloidosis may represent antibody formation. Furthermore, electrophoretic methods have been of value in controlling the separation of trophic hormones from extracts of the anterior pituitary gland and in proving their purity.

The book details many other investigations, including chapters on latex and on the surface chemistry of cells and a discussion of therapy by electrophoretic transport of drugs and allergens through the skin.

A book covering the rising curve of research in a new field can hardly be written in leisure, and suffers in being out of date before the ink is dry; and a more compendious index might have increased its usefulness. These inadequacies are small beside the value of a much-needed monograph. The first half of the book (theory and methods) is indispensable to those who undertake electrophoretic studies or the critical evaluation of those of other men. The entire book is worthy of perusal by clinicians and investigators who wish to keep abreast of the biophysical aspects of disease.

NUMBER 6

SO CALLED "ATYPICAL PNEUMONIA" AMONG COLLEGE STUDENTS*

ANDREW W. CONTRATTO, M.D.†

CAMBRIDGE, MASSACHUSETTS

THERE has recently been noted among the students at Harvard University a marked increase in the incidence of an acute infection the etiology of which is little understood. Reimann^{1, 2} in 1939 called attention to isolated cases of a form of pneumonia in adults, apparently not caused by bacteria or by the virus of epidemic influenza. From 2 of the cases that he reported during the years 1938-1939 a filterable infectious agent was recovered. Smiley, Showacre, Lee and Ferris³ in the same year reported what they called "acute interstitial pneumonitis" in the student body of Cornell University. Murray⁴ reported a group of so-called "atypical pneumonias" occurring in Harvard students during the winter of 1936-1937. Within the past year, Finland and Dingle^{5, 6} discussed in great detail the various types of pneumonias and included in their discussion all the known pneumonias not caused by a definite bacterial infection. They reviewed the literature thoroughly for the types of pneumonia which had been more frequent in recent years and in which the pulmonary lesions were not due to the common pathogenic bacteria. They called attention to the fact that atypical pneumonia was almost entirely limited to adolescents and young adults. They also believed that little is known about the mode and manner of spread of this illness. The general consensus, they said, is that it is transmitted by contact but is not highly communicable. Although the disease is commonly referred to as "virus pneumonia," no one of these authors was able to prove or disprove that these somewhat related pulmonary diseases are due to a virus. They were all in agreement, however, that it is not of bacterial origin.

Since July, 1942, there have been admitted to the Stillman Infirmary some 75 cases of atypical

pneumonia, proved by clinical and roentgenologic evidence. No case was considered so proved unless the symptoms were fairly typical and x-ray examination of the chest showed changes compatible with atypical pneumonia. This a great increase over any number admitted in recent years. During the academic year of 1938-1939, of 2128 admissions there were 81 cases diagnosed as bronchopneumonia. During 1939-1940, of the total of 1943 patients admitted only 15 were diagnosed as having bronchopneumonia. During 1940-1941, during which time there were 2104 admissions, only 7 cases were diagnosed as bronchopneumonia. In 1941-1942, there were 15 diagnoses of atypical pneumonia among 1595 admissions. From July 1 to December 20, 1942, there were 75 cases of atypical pneumonia among some 884 admissions. This is 8 per cent of the total admissions in this period, a startling percentage indicating the high incidence of this illness at the present time.

The average age of patients in this series, all of whom were males, was twenty, the youngest patient being seventeen and the oldest twenty-four. This does not mean that the illness is confined entirely to this age group, it may occur in older persons, although perhaps with less frequency.

INFECTIOUSNESS

The question of infectiousness of this disease is most debatable at the present time. It is the belief of some^{1, 2} that it is highly contagious, but from a practical viewpoint, considering our experience during the last few months, it is surprising that none of the personnel of the institution caring for these patients have been ill although no extraordinary precautions were taken. Moreover, there was no case in which both of two roommates were afflicted with the disease. In one case, a boy who had been exposed to atypical pneumonia patients in an open ward was readmitted two

†Physician, Department of Hygiene, Harvard University associate, Peter Bent Brigham Hospital; assistant in medicine, Harvard Medical School.

weeks later with the disease. For the most part these patients were kept in the same ward as were students with ordinary respiratory infections and a mixture of other unrelated illnesses. With this experience, it is most difficult to interpret accurate-

feverishness and, rarely, extreme lethargy. In a few cases cough, although of a minor character, was present, and in some a history of a head cold of several days' duration was obtained. The onset of the disease was insidious, chest pain was absent

FIGURE 1. Charts of Case 1 (left) and Case 2 (right).

ly the infectiousness of the disease, and it has not seemed worth while to use infectious precautions such as are required for the handling of a highly contagious illness. It may well be that, as suggested by Bock⁷ and Reimann,² this infection is a manifestation in one patient of atypical pneumonia, whereas in another it manifests itself in a no more serious way than a "cold." On this assumption, it does not appear to be necessary to use extraordinary precautions in handling cases of atypical pneumonia when the free movement of those suffering from "colds" is permitted. The major precaution is, perhaps, the simple requirement that none of the staff shall appear on duty while afflicted with an acute respiratory infection, regardless of its severity.

SYMPTOMS

The symptoms were extremely variable but the absence in most cases of any symptoms referable to the respiratory system was noticeable. The predominating symptoms at the time of admission were easy fatigue, general malaise, muscle pains, headache, an alternate feeling of chilliness and

in all cases, and cough in the great majority of cases was absent or minor with the exception of several cases to be discussed later. In no case was there expectoration of sputum of any noteworthy amount, or of prune-juice or bloody sputum.

PHYSICAL EXAMINATION AND HOSPITAL COURSE

The physical examination at the time of admission showed an average temperature of 102°F., the lowest being 100 and the highest 104. The remainder of the examination was negative unless the student had had the illness for five to six days before admission, in which case coarse rales could be heard in some area of the lung field. The white-cell count was within the normal range with one or two exceptions, when it was 14,000 or 15,000 on the first day but was below 10,000 on the second. The initial elevation in these exceptions may have been due to dehydration. A noticeable leukopenia was absent in the great majority of cases, the lowest count being 5200 and the average 6800. The differential count and the blood smear were characteristically in the normal range. The only possible way of making a diag-

nosis in the early stages is by means of x-ray examination of the chest. In some cases the findings were normal during the first few days of the illness (Case 1) and for three or four days after admission, although the symptoms of general

usual first physical sign was the appearance of coarse rales, most often on the fifth or sixth day, but sometimes as late as the tenth. Frequently at the time of the appearance of the rales the patient was feeling better and the temperature was

FIGURE 2 Case 1.

The film on the left was taken on the second hospital day. There is linear increased density in the left upper lobe; otherwise the chest appears normal. The one on the right, taken on the fourth hospital day, shows an area of diffuse haziness occupying the left infraclavicular region that is consistent with pneumonia.

malaise, chilliness and so forth were marked and the temperature was high.

There seemed to be no predominance as to the area involved, although generally speaking the bases of the lungs were more frequently involved than were the upper and middle lobes. The amount of consolidation shown by x-ray examination was extremely variable. In some cases, the roentgenologic examination showed only a small area of consolidation without further progression, but in others the x-ray film was most startling in its appearance—in fact, so much so that it closely resembled the picture of miliary tuberculosis (Cases 2 and 3). The x-ray appearance was in most cases that of patchy consolidation throughout the part of the lung involved, but in approximately 20 per cent of the cases it showed frank consolidation of one lobe or another (Case 4).

In all cases except those showing lobar consolidation by roentgen ray, bronchial breathing or other signs of consolidation were absent, and the

on the down grade. Dyspnea was not present in the great majority of cases, and the respiratory rate in all except a few cases was not increased beyond the point that one would expect in a patient with fever. In some cases a rapid respiratory rate was noted (Case 3), but in these patients it was due to a shallow, panting respiration rather than to true dyspnea. The shallow, rapid respiration was due largely to the fact that deep breathing or even normal chest excursion precipitated paroxysms of coughing. Cyanosis was present in only 2 cases, and then to only a moderate degree.

The average period of hospitalization was ten days, the shortest being six days and the longest thirty days. The short hospitalization of some patients does not mean that the disease was completely over in this time. Most of the patients had been ill for four or five days before admission, and in other cases they were discharged home for convalescence before they could be considered ambulatory.

symptoms being general malaise, pains in the muscles, slight chills and fever, and a mild cough. On admission, the temperature was 104°F. (Fig. 4), and physical ex-

without benefit. The first clinical signs in the chest were heard on the 6th hospital day, when signs of frank consolidation were observed at the right base. On the

FIGURE 5. Case 3.

The film on the left, taken on the second hospital day, shows haziness in the left lower lobe lateral to the heart. That on the right, taken on the tenth day, shows a miliary process involving the entire left lung, which is most marked at the base; there is also a miliary process in the upper portion of the right lung, probably in the upper lobe.

FIGURE 6. Case 4.

This film, taken on the seventh hospital day, shows complete consolidation of the right middle lobe and of a large portion of the right lower lobe.

amination was negative; the white-cell count was 16,700, with a normal differential. A count the following day was 8000, with 90 per cent neutrophils. The patient was started on large doses of sulfathiazole 2 days after admission. This medication was continued for 3 days

following day, an x-ray film (Fig. 6) revealed complete consolidation of the right middle lobe and of a large portion of the right lower lobe. The patient continued to run a rather high temperature, which gradually subsided by lysis on the 13th hospital day. On the 18th day, moist rales at both bases were still present. The lung signs gradually abated, and the chest became clear one week before discharge. This case is most interesting in that the white-cell count continued to rise. It reached a high of 22,800 on the 13th day, when the temperature was normal. Furthermore, an eosinophilia developed, which went as high as 26 per cent. The count did not return to normal until the 32nd day, 1 week after all the chest signs had disappeared, and 19 days after the temperature had returned to normal. The cause of this queer blood picture could not be explained.

SUMMARY

A clinical study of so-called "atypical pneumonia" among 75 college students is reported. The patients were males and ranged from seventeen to twenty-four years of age, with an average age of twenty years. The average period of hospitalization was ten days, but the disability period averaged twenty-one days.

There were no serious complications and all the patients recovered without incident. Four cases, which were somewhat unusual in character, are discussed in detail, with clinical charts and roentgenologic data.

INHALATIONAL THERAPY IN THE TREATMENT OF SERIOUS RESPIRATORY DISEASE

MAURICE S. SEGAL, M.D.*

BOSTON

THE use of oxygen for the treatment of various types of anoxemia has increased tremendously. One generally appreciates that every physiologic function is only as efficient as its supply of oxygen. Reviews of the physiologic principles on which oxygen therapy is based have been made by Haldane,¹ Haldane and Priestly,² Lundsgaard and Van Slyke,³ Peters and Van Slyke,⁴ Barcroft,⁵ Meakins and Davies⁶ and others. Reviews of its practical application have been made by Boothby and his associates,⁷⁻⁹ Barach and his associates,¹⁰⁻¹² and others.

The use of mixtures of helium and oxygen for the treatment of the various anoxemias associated with respiratory and cardiac disease has increased largely through the investigative efforts of Barach. He¹³ has repeatedly demonstrated improvement in vital capacity, marked reduction in pulmonary ventilation, diminished tidal volume, diminished residual air and increased expiratory and inspiratory velocity rates with properly directed inhalational therapy in patients with asthma and emphysema. Barach and his associates have stressed the value of oxygen and helium and oxygen mixtures with and without positive pressure in a large series of papers based on experimental and clinical observations. The use of these mixtures under positive pressure has not become so widespread as it should have. Most clinicians are discouraged by the technical details and apparatus necessary for this type of inhalational therapy. However, its value as an adjunct in the management of the desperately ill patient with respiratory disease should overcome this attitude.

Equipment for Inhalational Therapy

The following are the more commonly used methods of administering oxygen: the nasal or nasopharyngeal catheter, oxygen face masks and tents and the various types of enclosing tents.

*From the Department of Medicine, Tufts College Medical School and the First and Third Medical Services, Boston City Hospital.
†Assistant professor of medicine, Tufts College Medical School and visiting physician, Boston City Hospital, June or visiting physician, Beth Israel Hospital.

Each method has its special advantages and disadvantages. With the above methods oxygen can be given in concentrations of 40 to 75 per cent. With the new B. L. B. inhalation mask and oxygen flows of 5 to 12 liters per minute, very high concentrations of oxygen can be administered quite economically.

Eckman and Birch¹⁴ have described in detail the various types of apparatus that they found useful. The helium oxygen pressure apparatus is a most effective one for giving oxygen or helium and oxygen mixtures with or without positive pressure. The percentage concentrations of the mixtures can be exactly controlled. Positive pressures up to 6 cm. of water can be applied to the inner surface of the lung during both inspiration and expiration. The apparatus consists of a gas tight motor blower, two canisters for the carbon dioxide absorber, a rheostat to determine the volume of air flow and its temperature, tubal connections, an ice containing cabinet and a plastic hood in which the patient's head lies, with closure made by a soft-rubber band collar. In this rebreathing circuit only the oxygen is used up.

In a recent paper Birch and Molomut¹⁵ describe a modification of the Birch-Eckman¹⁴ mask. This new type of injector mask is metered for positive pressures up to 4 cm. of water in the expiratory phase only. Along with the injector (oxyator principle) it may be used to deliver 40 to 95 per cent oxygen or helium and oxygen mixtures with or without positive pressure during expiration. It can be used to supplement the above-described hood apparatus. The mask is a credit to the ingenuity of the authors. Both the hood and the mask apparatus were employed in the present series.

Use of Helium

Helium is an inert, colorless, odorless, non-combustible gas of low molecular weight.¹⁶ It has a specific gravity one seventh of that of nitrogen and one eighth of that of oxygen. It has a low

coefficient of solubility, being 40 per cent less soluble in water than is nitrogen. It is nearly three times more diffusible than nitrogen. Hence very little helium is dissolved or lost in the body. In comparison, nitrogen under pressure is much more soluble in body fluids and furthermore has an affinity for lipids.

In 1934 Barach¹⁷ proved the biologic inertness of helium. A mixture of 80 per cent helium and 20 per cent oxygen is one third as heavy as air. Its lightness suggested to Barach that it could be moved to and from the lungs in obstructive dyspneas more easily than air. Furthermore, a lighter-than-air mixture will go through a constricted orifice more easily. The pressure required for the movement of an 80 per cent helium and 20 per cent oxygen mixture would be about half that required for air through a similarly constricted orifice. It should be possible with helium and oxygen mixtures to compensate for approximately a 50 per cent constriction in the lumen of the tubal respiratory tract. The more localized the obstruction, the better the effect. This saving in respiratory effort may be of life-saving value.

The chief use of helium-oxygen mixtures is in the treatment of obstructive dyspnea from the larynx to the bronchiole (Barach^{17, 18} and Eversole¹⁹). It should always be given a trial in any type of respiratory obstruction in an effort to avoid tracheotomy, with its inherent complications. Helium when mixed with oxygen decreases the effort required for pulmonary ventilation, and lowering of the negative intrapleural pressure follows. Addition of positive pressure further accentuates this lowering.

The proper percentage of oxygen in the helium-oxygen mixture depends on the degree of anoxemia. The proper percentage of helium depends largely on the degree of mechanical obstruction interfering with the inflation of the alveoli. By using separate tanks, one containing 80 per cent helium and 20 per cent oxygen and the other 100 per cent oxygen, connected by a Y tube to either the hood or the mask apparatus, the desired percentage of the mixture can be changed at will to suit the patient's physiologic needs. At least 20 per cent oxygen must be administered. It is doubtful whether helium will be valuable if the mixture contains more than 33 to 35 per cent oxygen. Continuous residence in the hood may be maintained without much discomfort for many days. In one of Barach's reported cases the patient required helium-oxygen therapy under positive pressure for six days. The metered mask may be kept on for one to three days, and perhaps longer with proper rest periods. The problem of length

of residence in hood or mask varies with the degree of anoxemia, dyspnea and respiratory fatigue and the presence of psychic factors. The higher percentages of oxygen should not be used continuously, for pulmonary irritation has been described. The change from hood to mask or oxygen tent should be gradual with a progressive reduction in the percentage of oxygen, or intermittent treatment should be carried out before complete cessation.

Treatment Of Pulmonary Edema With Positive Pressure

Pulmonary edema occurs frequently in a wide range of respiratory and circulatory diseases and usually constitutes an acute medical emergency. It has been found clinically that positive-pressure inhalation of oxygen or helium and oxygen clears up the signs of pulmonary edema promptly. Barach²⁰ in his most recent paper once again demonstrated the value of properly directed positive-pressure inhalational therapy in 5 patients critically ill with pneumonia. He states that positive pressure is like putting a finger on the capillaries and stopping their oozing.

Barach²¹⁻²³ has summarized the sequence of events that follow resistance or obstruction to inspiration. There is at first a rapid and progressive increase in the intrapleural negative pressure in order to force sufficient air into the lung. Other changes, characterized by pulmonary edema and final respiratory failure, may follow. Barach and his associates^{24, 25} have repeatedly demonstrated that when oxygen or helium-and-oxygen mixtures are taken under positive pressures, the abnormally elevated negative intrapleural pressure is diminished and dyspnea is alleviated. Nature provides a helpful internal mechanism, as observed by Barach, in the severe asthmatic patient pursing his lips in expiration, and in the pneumonic patient grunting and groaning with expirations. The expiratory grunt maintains a more patent airway and helps to prevent pulmonary edema.

Properly controlled positive pressure is extremely useful in the management of pulmonary edema. The moist, bubbling rales have been seen to clear up within fifteen to forty-five minutes in a series of patients with underlying bronchial asthma, pneumonia, left-ventricular failure, mediastinal obstruction and gas poisoning. The signs of pulmonary edema usually remain absent as long as the pressure is applied or until the original cause has been removed. The application of a gentle internal distending force serves to keep the bronchioles patent and opposes the hydrostatic pressure within the capillaries.

Generally, positive pressures of 2 to 6 cm. of water are sufficient for preventing or treating

pulmonary edema Pressures above 6 cm may diminish the return flow of blood to the right side of the heart Theoretically, shock may be considered a contraindication to the use of positive pressure

Inhalation of Vaporized Bronchodilator Solutions

The value of oral inhalations of vaporized sprays of various bronchodilator solutions with the use of a hand bulb atomizer was established on a sound basis by Graeser and Rowe²⁶ Richards, Barach and Cromwell²⁷ described the technique of continuous vaporization of bronchodilator solutions for the treatment of bronchial asthma, emphysema, acute bronchiolitis and various so-called "virus pneumonias" They used 1 or 2 cc of 1:100 epinephrine and 1 per cent Neo-Synephrine, alone or in combination The solution was placed in the vaporizer and oxygen was passed through it from the pressure tank at the rate of 4 to 7 liters per minute The patient simply held the nozzle of the vaporizer in his mouth and breathed quietly This therapy was repeated every three or four hours Clinical improvement was striking The vital capacity and maximum breathing capacity increased in the majority of cases

Neo-Synephrine is an effective vasoconstrictor of the mucous membrane of the tracheobronchial tree but a poor bronchodilator Refractoriness to it does not occur Epinephrine serves as an effective bronchodilator The combined effect relieves bronchial spasm and loosens tenacious mucus As a rule following such therapy the patient coughs and raises mucus and sputum that previously he could not expectorate Subjective improvement follows, and frequently the obstructive asphyxial picture is relieved after plugs are brought up from the tracheobronchial tree

This type of therapy is of greatest value in status asthmaticus It should be used, however, in all types of respiratory disease in which the mechanical factor of obstructive dyspnea due to plugging or spasm of the tracheobronchial tree exists Untoward results from such therapy are extremely uncommon If the patient is too ill to be removed from the tent or hood, the nebulizer can be passed through the tent opening or hood sleeve directly into his mouth

* * *

Based largely on the work of Barach and his associates, physiologically directed therapy in the management of patients ill with obstructive respiratory disease of varied etiology has been well established A similar program was offered successfully in a series of desperately ill patients Repeated bronchial relaxation was accomplished whenever indicated, by the use of rectal amino

phyllin, dilaudid, iodides, nebulization therapy with Neo-Synephrine and epinephrine, and proper humidification High concentrations of oxygen and of helium and oxygen mixtures were given, with and without positive pressures as indicated, through the new Barrich-Molomut mask and re-breathing hood apparatus The patients were critically ill and moribund at times before therapy was started The sole criterion for successful therapy was objective and subjective evidence The condition of the patients did not permit more definite studies

The present report covers the first 4 patients treated The above therapy in part or in entirety has been employed in a larger series of varying cardiorespiratory diseases and will be reported in other communications

The first patient was desperately ill with an asphyxial obstructive type of status asthmaticus, the second patient with a virulent bilateral miliary type of virus pneumonia with progressive anoxemia, dyspnea and pulmonary edema; the third patient with a bilateral virus pneumonia with underlying bronchial asthma, complicated by a massive atelectasis of the right lower lobe with mediastinal shift, and the fourth patient with a Type 7 pneumonia involving practically all the lung tissue, septicemia, a toxic type of auricular fibrillation and other complications Progressive dyspnea, anoxemia and cyanosis had occurred in spite of the conventional methods of therapy

The program of physiologically directed therapy was begun only after all other methods had failed and the patients were desperately ill In the 3 pneumonia patients the improvement was progressive over a period of two to five days The diminished toxicity was striking after the third or fourth day The anoxemia, cyanosis and dyspnea were controllable almost from the outset of therapy The usual troublesome cough in the 2 virus pneumonia patients was controlled successfully with supplemental inhalational therapy Pulmonary decompensation was effectively controlled and convalescence was much more rapid than expected if one were to judge solely by the severity of the clinical picture

CASE REPORTS

CASE 1 The patient a 35-year-old physician, had been well except for seasonal hay fever and frequent mild upper respiratory infections until November 10 1942 On that date he complained of rhinorrhea headaches chilliness vague muscular aches and pains, and abdominal discomfort These symptoms progressed during the following 5 days On November 15 he complained of a slight cough associated with tightness through the chest and some difficulty in breathing largely in the expiratory phase The dyspnea soon became more marked, with characteristic asthmatic wheezing From November 17

to 19 the dyspnea and wheezing increased in severity in spite of barbiturates, adrenalin and intravenous aminophyllin. The chest remained fixed in inspiration and was emphysematous; over it, inspiratory and expiratory wheezes were heard, with occasional moist rales at the bases. The picture soon became that of the cyanotic, asphyxiated, obstructed, asthmatic patient.

The patient was admitted to the hospital on November 19. During the following 24 hours he was given repeated sedatives, adrenalin, aminophyllin, and helium by nasal catheter. In spite of these procedures he suffered three severe attacks of bronchospasm with an intense obstructive asphyxial picture. His condition was desperate. On November 21 he was placed in a helium-oxygen hood rebreathing apparatus and was given a mixture of 80 per cent helium and 20 per cent oxygen under positive pressure. This proved to be the turning point in therapy and the patient was soon able to get his first rest. He remained in the hood for 2 days. This therapy was further supplemented by the intermittent inhalation of mixtures of 1 per cent Neo-Synephrine and 1:100 epinephrine with 100 per cent oxygen. In addition he received dilauid, aminophyllin by the rectal route, and supportive intravenous saline and glucose.

Under this program the patient soon improved. His cough became productive of large plugs of mucus. The dyspnea, cyanosis and anoxemia were properly controlled by varying the helium and oxygen percentages. The lung fields cleared progressively. A chest film taken on November 23 suggested emphysema, a plugged bronchus on the left and a mediastinal shift toward the right. After a few days the patient was able to get along without further helium therapy, but the inhalation sprays were continued for 3 days.

The patient was discharged from the hospital on November 29. The lung fields were clear throughout but hyper-resonant. The white-cell count and the percentage of eosinophils were still elevated, however. During the following 10 days at home he continued to complain of intermittent rhinorrhea and mild attacks of tightness through the chest, with slight wheezing. This was usually accentuated by overexertion and exposure to cold, dust or tobacco smoke. A repeated chest film was essentially normal except for slight emphysema and accentuated bronchial markings. The final diagnosis was acute upper-respiratory infection and status asthmaticus with intense dyspnea, anoxemia and cyanosis.

Comment. This desperately ill patient recovered under a physiologically directed program consisting of helium-and-oxygen mixtures under positive pressure, and inhalational sprays of Neo-Synephrine and epinephrine with oxygen. The relief from the dyspnea and anoxemia was most striking from the outset of this program.

CASE 2.* The patient, a 35-year-old, unmarried woman with an uneventful past history, became ill on December 2, 1942. At onset she complained of aches and pains, malaise, shaking chills and fever. During a 10-day period at home persistent cough, fever up to 105°F., progressive cyanosis and dyspnea characterized her course. There was no chest pain or rusty sputum. In spite of the giving of oxygen by facial mask and sulfadiazine, difficulty with respiration and anoxemia progressed. The patient was seen by Dr. Maxwell Finland in consultation and removal to the hospital was advised.

*This case is reported through the courtesy of Dr. Maxwell Finland.

On admission on November 12, the patient was acutely ill, dyspneic, dehydrated, drowsy, incoherent and cyanotic. The temperature was 101°F., the pulse 120, and the respirations 30. The respiratory movements were rapid and shallow. The lungs revealed a variety of expiratory squeaks and medium to coarse rales, largely limited to the top of both lungs anteriorly and the lower half of both lungs posteriorly. The abdomen was distended and the urinary bladder full. The white-cell count was 16,200, with 86 per cent polymorphonuclear leukocytes and many toxic granules. The red-cell count was 4,460,000 and the hemoglobin 65 per cent.

The admission diagnosis was bilateral atypical pneumonia. Chemotherapy was discontinued, and oxygen was given by nasal catheter and later by mask, and fluids by clysis and general supportive care. A sputum culture later showed many colonies of staphylococci by direct inoculation on blood agar. Sulfadiazine was resumed on December 16. An x-ray film revealed a bilateral, diffuse, miliary type of virus pneumonia.

During the 1st week in the hospital the patient's course was characterized by progressive dyspnea, cyanosis, abdominal distention and periods of irrationality and urinary incontinence. The temperature remained between 101 and 103°F., the respirations at 48 and the pulse at 120 to 140. On the 16th day of illness the patient's condition was desperate and a program of positive pressure with oxygen and helium-oxygen mixtures was finally begun.

For 15 hours a B. L. B. mask was arranged to give positive pressure in the expiratory phase of respiration, with flows of 10 to 12 liters per minute of oxygen or helium-oxygen mixtures. The respiratory rate was slowed and the patient managed to get a few hours of rest during the first night. On December 19 a new Barach mask metered for positive pressure was used and this was continued for 5 hours. The patient was then placed in a helium-oxygen hood. It is significant that the respirations had dropped to 28 before entering the hood, and that gurgling and bubbling rales heard over the top of both lungs cleared up promptly with positive pressure.

The patient remained in the hood for 3½ days, and had her first hours of comfortable sleep there. During this time she received mixtures of helium and oxygen in varying percentages depending on the anoxic or obstructive factor. In addition she received inhalational sprays of mixtures of 1 per cent Neo-Synephrine and 1:100 epinephrine every 4 hours, with flows of oxygen of 4 to 6 liters per minute. The mixture was generally introduced through the sleeve of the hood, with the nurse holding the nebulizer in the patient's mouth or the patient holding the nebulizer between her lips. Further therapy consisted of 1/64 gr. of dilauid twice daily as needed, and potassium iodide orally. The abdominal distention was strikingly relieved at the onset of therapy when the patient received straight oxygen. Sulfadiazine was stopped on December 20 because of diminished urinary output. At various times definite prolonged expiratory wheezes were elicited over both lung fields.

The general course was one of slow but progressive improvement. While the patient was in the hood the temperature ranged around 99.6°F. rectally, the pulse between 96 and 112, and the respirations between 28 and 32. She was considerably less toxic. Her color remained pink and breathing was not labored.

The cough soon became productive. The sputum was at first sticky and glairy, and later less tenacious. After 3½ days in the hood she returned to the Barach-Molomut mask with positive pressure of 4 cm in the expiratory phase only, using largely 95 per cent oxygen alone. This was continued for 2 days and thereafter intermittently for 6 days. During these periods the percentage of oxygen was slowly reduced. Nebulization therapy was continued, however, until December 31. Scattered medium moist rales could still be elicited at the bases posteriorly on January 2, 1943, the day the patient was allowed up in a chair. She shortly became ambulatory and was discharged home to convalesce on January 5. During the first 2 weeks at home she had two attacks of sudden breathlessness at night, relieved by Propadrine Hydrochloride. Scattered expiratory wheezes could be elicited. This bronchospasm soon cleared up however.

Comment. A desperately ill patient with bilateral virus pneumonia, unresponsive to usual methods of care, responded characteristically to a program of physiologically directed inhalational therapy consisting largely of mixtures of helium and oxygen under positive pressure. The most striking observation was the relief from cerebral anoxemia and respiratory failure which appeared imminent at the beginning of therapy.

Case 3.* The patient, a 25-year-old intern with a past history of autumnal asthma, was admitted to the hospital because of a 4-day history of sore throat, headache, malaise, anorexia, abdominal distress, fever, substernal tightness and nonproductive cough.

Physical examination revealed a flushed, perspiring young man with slight expiratory wheezing. The temperature was 101°F, the pulse 86, and the respirations 24. The outstanding findings were in the chest, which was increased in the anteroposterior diameter, with the breath sounds distant. There was slight dullness at both bases, with bronchovesicular breathing but no rales. In constant wheezes were heard throughout both lung fields. A chest film revealed haziness in the right lower and left lower lung fields.

The laboratory data revealed a slightly elevated white cell count. Throat, sputum and blood cultures were negative for pneumococci.

The diagnosis on entry was an atypical pneumonia. The patient was treated symptomatically. In the course of the first few days the temperature rose to between 102 and 104°F. On the 6th day, because of failure to respond and because of increasing signs of consolidation, he was given full doses of sulfadiazine. Nevertheless there was a gradual rise in pulse and respiratory rate and no drop in temperature. Paroxysms of nonproductive coughing then developed accompanied by cyanosis and exhaustion. Both the clinical and x-ray impressions were those of an extensive pneumonia involving the entire right lung and the left lower lung. The mediastinum was shifted to the right and there was apparently some degree of atelectasis of the right lower lobe. At times there was definite evidence of bronchospasm, only partially relieved by epinephrine.

The clinical course was progressively downhill with increasing anoxemia, cyanosis and dyspnea in spite of oxygen therapy with the B. L. B. mask and oxygen tent. On December 27 the patient appeared desperately ill. Loud bubbling rales were heard throughout both sides

of the chest in both phases of respiration, with marked lengthening of expiration. A program of therapy was begun consisting of nebulizer inhalations of epinephrine and Neo-Synephrine, rectal aminophyllin and positive pressure helium-oxygen mixtures. Within 15 minutes after the patient was placed in the hood under positive pressure the bubbling rales disappeared and the respirations became easier. He soon fell asleep and awoke in an hour considerably refreshed.

He remained in the hood for 4½ days. Nebulization was generally carried out while in the hood. The mixtures of helium and oxygen varied depending on the degree of cyanosis and respiratory obstruction. The toxicity diminished strikingly and the temperature began to return to normal after the 3rd day. The pulse and respiratory rates became slower shortly after this program of therapy was begun. The troublesome cough was more easily controllable, less distressing and more productive. After residence in the hood the patient was placed in the Barach-Molomut mask with varying percentages of oxygen under positive pressure. These percentages were gradually reduced, and oxygen therapy was stopped on January 1, 1943. Nebulization therapy was continued for a few more days. He was permitted up on the 24th hospital day and was discharged home on the 30th day. The final diagnosis was bilateral atypical pneumonia with atelectasis of the right base and a mediastinal shift to the right, and acute bronchospasm.

Comment. A seriously ill patient unresponsive to the usual methods of care, responded characteristically to a program of inhalational therapy consisting largely of mixtures of helium and oxygen under positive pressure.

Case 4† The patient, a 44-year-old, married man, had had a chronic upper respiratory infection for 1 month prior to the present illness. Three days before hospital entry there occurred the sudden onset of marked malaise, repeated chills with high fever, cough productive of blood streaked sputum and pleuritic pain in the right lower chest. In the past a mild hypertension and renal lithiasis had been observed.

The admission physical examination revealed a markedly dyspneic, cyanotic, toxic and dehydrated middle-aged man. The temperature was 104°F, the pulse 120 and the respirations 30. There was dullness at both lung bases with diminished breath sounds and moist rales. The cardiac examination revealed no murmurs or enlargement. The rhythm was regular. The blood pressure was 140/70. The laboratory examination revealed a Type 7 pneumococcus in the sputum and also in the first blood culture. The white-cell count was 17,700, with 82 per cent polymorphonuclear leukocytes. The hemoglobin level and red-cell count were within normal limits. A urine examination was entirely negative and showed a specific gravity of 1.029.

The admission diagnosis was lobar pneumonia and septicemia due to a Type 7 pneumococcus. The patient was started immediately on 4 gm of sulfadiazine, with 1 gm every 4 hours thereafter. During the first 4 days the temperature varied between 102 and 104°F, the pulse between 110 and 130 and the respirations between 25 and 30. On the 5th day the temperature climbed to 105°F, the pulse to 150 and respirations to 40. X-ray studies revealed an extension of the process from the right base to the right upper lobe. The blood sulfadiazine level

*This case is reported through the courtesy of Drs. Harry L. Nenthal and H. J. Blumgart.

†This case is reported through the courtesy of Dr. Herman Meertson.

was 9.0 mg. per 100 cc. The patient was extremely anoxic and demonstrated a moderate degree of expiratory stridor in spite of oxygen therapy with both B. L. B. and Barach-Eckman masks. He was then given a Type 7 antipneumococcus serum—150,000 units on the 1st day and 270,000 units on the 2nd day. Because of the persistence of anoxemia, cyanosis and mental confusion and the appearance of respiratory fatigue, a program of positive-pressure oxygen was agreed on. The patient was first placed in the hood rebreathing apparatus, with 100 per cent oxygen under positive pressure of 2 to 5 cm. of water. He remained in the hood most of the time during the following 4 days. During the rest of the time this program was continued in the Barach-Molomut mask. The temperature fell gradually during these 4 days and the respirations were much less labored. Cyanosis and anoxia were much less evident. However, auricular fibrillation developed with a radial rate of 150. The white-cell count rose to 56,000, urine examinations revealed albuminuria with a fixed specific gravity of 1.010, and the nonprotein nitrogen rose to 81 mg. per 100 cc. The patient presented signs of upper abdominal distention, which was relieved with a Levine tube and gastric lavage. Positive-pressure oxygen was discontinued on the 5th day after all signs of respiratory fatigue and tracheal rales had subsided. Oxygen therapy was continued, using the Barach-Molomut mask with mixtures of oxygen varying from 80 to 90 per cent depending on the degree of anoxemia.

The auricular fibrillation was controlled by digitalis. Because of the findings of renal insufficiency, chemotherapy was omitted. During the next week the temperature again began to rise slowly in a fluctuating fashion, reaching 103°F. X-ray examination revealed persistence of signs in the right upper and middle lobes. The white-cell count gradually dropped to 14,000 and the nonprotein nitrogen fell to 61 mg. per 100 cc. The urine showed persistent albuminuria, with specific gravities averaging 1.010. In the terminal 5 days progressive disorientation and confusion developed. Because of the cerebral symptoms it was thought advisable to continue the oxygen therapy in the oxygen tent. During the last 24 hours in spite of this therapy the patient developed rapid pulmonary edema and respiratory failure and died on January 31.

The autopsy revealed massive bilateral pneumonic involvement, with bronchiectatic abscesses in the right base, diffuse fatty infiltrative changes in the renal tubules and an acute bacterial endocarditis (terminal, Type 6 pneumococcus).

Comment. A desperately ill 44-year-old man with a Type 7 pneumonia and septicemia developed progressive signs of anoxemia, cyanosis and respiratory fatigue in spite of the usual methods of oxygen administration. These were adequately controlled during a 4-day period with a program of positive-pressure oxygen. However, progressive signs of renal insufficiency, cerebral psychosis and pneumonia spread and acute bacterial endocarditis resulted in death.

SUMMARY

A report is made of the use of positive-pressure inhalational therapy with mixtures of helium and oxygen and oxygen alone in the treatment of 4 patients desperately ill with respiratory disease.

The importance of supplemental inhalational therapy of mixtures of Neo-Synephrine and epinephrine, vaporized with a continuous flow of oxygen, is demonstrated.

Helium-oxygen and oxygen mixtures under positive pressure have a definite value in the therapy of pulmonary edema of varied etiology, bronchial asthma, acute bronchiolitis, acute fibrinous tracheobronchitis, severe emphysema, pulmonary fibrosis, laryngospasm, laryngeal diphtheria with obstruction, severe obstructive whooping cough and certain pneumonias or gas poisonings.

All cases of obstructive respiratory disease demonstrating anoxia, cyanosis, asphyxia, pulmonary edema or progressive intractable dyspnea, alone or in combination should have a trial with the above therapy.

TOXIC PSYCHOSIS AND DEATH ASSOCIATED WITH POTASSIUM THIOCYANATE THERAPY*

Report of a Case

JAMES SOLOMON, M.D.,† MILTON GREENBLATT, M.D.‡ AND GAYLORD PALMER COON, M.D.§

BOSTON

THE purpose of this article is to emphasize the toxicity of potassium thiocyanate and to present a case showing acute psychosis with a fatal outcome.

The literature contains many reports concerning the use of potassium thiocyanate, the most notable early references being those of Pauli¹ in 1903 and 1904, who first noted its hypotensive effect; Westphal² in 1926, who reawakened interest in the therapeutic possibilities of the drug; and Barker³ in 1936, who first emphasized potassium thiocyanate blood levels as a method of control of therapy.

The pharmacologic and therapeutic properties of this drug were first reviewed in 1925 by Nichols,⁴ who observed that it was highly toxic for guinea pigs, and that a few hours after administration of the drug there developed diarrhea, progressive loss of weight, marked evidence of spinal irritation, convulsions, coma and death. His experiments appeared to substantiate Bernard's original claim that potassium thiocyanate is a tissue poison.

A total of 9 fatalities have appeared in the literature. The first fatal case, reported by Lesser⁵ in 1898, was that of a magician who took the drug with suicidal intent. Death occurred within ten hours, and an autopsy revealed extensive necrosis and hemorrhage in the mucous membrane of the gastrointestinal tract. The second case, reported by Robert⁶ in 1906, was that of a woman who died twenty-eight hours after ingestion of this drug. There is some hesitancy in including this among the lethal group because of the inordinately small total dose of the drug allegedly taken (5 gr.). In

1916, Vintilesco and Popesco⁷ reported a toxic psychosis with delirium, convulsions, spinal rigidity, coma, anuria and death in two days after the intake of an estimated 100 gm. of potassium thiocyanate. Healy⁸ in 1931 reported 2 cases in each of which the patient had taken a total of 9 gm. of potassium thiocyanate for therapeutic purposes. In one case the lowering of the blood pressure was followed by marked weakness, collapse, semi-coma and death nineteen days after discontinuance of the drug. In the other case death occurred two weeks after discontinuance, following a similar train of symptoms. Goldring and Chasis⁹ mentioned 2 additional fatal cases, again associated with the therapeutic administration of potassium thiocyanate. In these cases there was an acute outbreak of mental symptoms, particularly confusion, incoherence, hallucinations and delirium, followed by excessive psychomotor activity, anuria and death. The last 2 cases reported were those of Garvin¹⁰ and Russell and Stahl,¹¹ both with pictures of toxic psychosis, overactivity and death. The latter authors emphasized the following characteristic clinical syndrome in mortal cases: first, there may be weakness (possibly due to lowering of the blood pressure), then outbreak of an acute toxic psychosis that primarily presents delirium, confusion, hallucinations and signs of irritation of the central nervous system. In all cases in the literature death has occurred within nine to fourteen days after the onset of the first symptoms. It is to be noted that the two blood levels recorded in association with the fatal cases were only 18.7 mg. and 21.6 mg. per 100 cc., and that in 1 case the total drug ingestion was as little as 5.6 gm., the patient receiving only 0.4 gm. (6 gr.) per day for fourteen days.

Although it is quite clear that in fatal cases symptoms of mental disorder are prone to precede exodus, mental symptoms in the course of potassium

§Associate in psychiatry, Harvard Medical School, chief medical officer Boston Psychopathic Hospital

thiocyanate therapy are by no means limited to fatal cases. Toxic central-nervous-system symptoms have been stressed from the earliest days of the use of the drug. McNeill¹² (1933), using it for the reduction of hypertension in state-hospital patients, noted in 4 out of 12 cases unsteady gait, confusion and rambling talk resembling that of an acute alcoholic intoxication. The mental reaction lasted for four to eight days after withdrawal of the drug. In 11 of 50 cases treated by Goldring and Chasis,⁹ the usual order of toxic symptoms was muscular fatigue associated with nausea, vomiting, disorientation and mental confusion, then frequently motor aphasia and hallucinations of sight and hearing. In ambulatory cases, they noted that the muscular fatigue was first complained of, but in bed patients this early warning of toxicity might pass entirely unnoticed, and it was not unusual for motor aphasia, mental confusion and even hallucinations to be the first sign of potassium thiocyanate intoxication. These authors believed that the toxicity was not especially a function of the dosage used. Other writers have stressed the fact that there may be markedly varying rates of excretion of potassium thiocyanate in different patients. Some are distinctly susceptible, and in some there is little or no margin of safety between the therapeutic and the toxic dose. Blood levels afford comparative safety in the control of therapy, yet cases have been reported of toxicity at supposedly safe levels (8 to 12 mg. per 100 cc.).

With regard to the manner in which potassium thiocyanate exerts its effects on tissues, the experiment of Robinson and O'Hare¹³ is noteworthy. By use of the Warburg apparatus, it was found that slices of liver exposed to potassium thiocyanate in a serum medium suffered a reduction of oxygen consumption of 40 per cent when the potassium thiocyanate concentration was 20 mg. per 100 cc. They suggest that there is probably a continuous moderate reduction of metabolism in all tissues. It is possible that nervous tissue and kidney tissue—in view of uremic exodus in several cases—are especially vulnerable.

CASE REPORT

W. S., a 46-year-old, married Negro, was admitted to the Boston Psychopathic Hospital on September 30, 1942, because of delusions and confusion. From the end of World War I, in which he saw military service, until his illness, he was employed as a letter carrier. He was known as a hard, steady worker and had no bad habits. Except for "pleurisy" of short duration each winter, he had been essentially without complaints.

In the spring of 1940, however, the patient was admitted to a hospital for the first time because of progressive dyspnea, chest pain and loss of weight of several months' duration. Physical examination at that time revealed

essentially a well-developed individual, moderately obese but not acutely ill. There was an arcus senilis arterio-venous nicking of the retinal vessels, elevated blood pressure (210/130) and slight cardiac enlargement, both clinically and by x-ray. An electrocardiogram strongly suggested coronary thrombosis with myocardial infarction. Laboratory analysis revealed normal blood, a nonprotein nitrogen of 40 mg. per 100 cc., a negative urine and adequate renal function by a dye-excretion test (phenol-sulfonephthalein). On bed rest and digitalization, the patient improved and after 1 month's hospitalization was discharged with a diagnosis of hypertensive arteriosclerotic heart disease.

For 2 years the patient was well and able to continue with his work, but in August, 1942, he again complained of shortness of breath, aggravated by exertion, and was readmitted to the hospital. At that time he was coughing, with production of occasional brownish sputum, and the left lower chest showed dullness. There was no peripheral edema. The blood pressure was 242/140. The heart was enlarged to the right and left as shown by x-ray, and an electrocardiogram revealed evidence of an old anterior-wall infarction. The blood was normal, and serologic tests for syphilis were negative. Urine examination showed persistent albuminuria (30 to 50 mg. per 100 cc.) and a low specific gravity (1.008 or less) on random specimens. The nonprotein nitrogen was 45 mg. per 100 cc.

The patient was put to bed. On August 14, potassium thiocyanate therapy was begun, 3 gr. three times a day, and a blood level of 8 to 9 mg. per 100 cc. was subsequently obtained. One and a half grains of digitalis three times a day was given for three days, followed by 1½ gr. daily. There was gradual disappearance of the cough and brownish sputum, and improvement of the dyspnea. On September 23, the 40th day of treatment, the patient was allowed out of bed. The blood pressure all this time had maintained itself around 210/130. On September 25, the potassium thiocyanate was discontinued. On September 30, the patient developed delusions that he was being shunned by everyone and was being threatened. He wandered about looking for a gun to protect himself. He was violent, overactive and disoriented and was transferred the same day to the Boston Psychopathic Hospital.

The mental status revealed an inattentive, perplexed, preoccupied patient who stared about in bewilderment. He gave his family history fairly coherently but was unable to tell the year of his marriage, the ages of his sons or what he had recently eaten. He could not give the date or the name of the hospital. He had no memory of the events that had led to his admission. His retention of digits was exceedingly poor, and his range of general information was inadequate.

About 12 hours after admission, the patient began to wander about the ward praying loudly and fervently, and exposing himself. He became resistive and combative and failed to grasp the significance of his surroundings. On October 2, blood studies revealed that the potassium thiocyanate level was 18.9 mg. per 100 cc. and the nonprotein nitrogen 70 mg. During the next few days the patient went rapidly downhill, showing excessive psychomotor activity and requiring constant restraint. He developed coma and increasing uremia. On October 8, at which time the potassium thiocyanate level was 24 mg. per 100 cc. and the nonprotein nitrogen 130 mg., he suddenly died. Death occurred on the 55th day after

the beginning of potassium thiocyanate treatment, 14 days after the drug was discontinued, and 9 days after the onset of mental symptoms. The total amount of the drug administered was 25 gm

COMMENT

Essentially, this patient had a past history of hypertension and two episodes of congestive failure requiring hospitalization. On the second hospitalization, it was evident that he had developed albuminuria and a low urinary specific gravity. After several weeks he was sufficiently improved to be up and about. He had received treatment with potassium thiocyanate for forty-two days and it was then omitted because of his improvement. Five days later, however, he suddenly developed a toxic psychosis, went downhill rapidly, showed excessive psychomotor activity and died in uremia. Potassium thiocyanate levels taken two days after the onset of psychosis were elevated beyond the therapeutic range.

In cardiovascular renal disease, death from uremia is not uncommon. In this case the patient was markedly improved with treatment but suddenly took a dramatic turn for the worse. This course of events may conceivably occur in uncomplicated cardiorenal disease, but it seems quite likely that in the present case potassium thiocyanate intoxication played a significant part in the slump and ultimate death. This is also suggested by the sudden appearance of toxic psychosis while the patient was presumably getting well, and by the marked resemblance of the whole picture to that observed in cases of potassium-thiocyanate intoxication described in the literature. This syndrome some authors regard as characteristic of fatal poisoning. It is difficult to evaluate the exact part played by the potassium thiocyanate, and indeed it is possible that several factors are operative, including the renal impairment, elevated potassium thiocyanate blood level and special tissue vulnerability. There is not yet full understanding of the sudden elevations in the blood levels of potassium thiocyanate that can occur not only in patients who receive constant doses of the medication, but even—as in this case—after the drug has been discontinued.

In view of the experience thus far, it seems important to bear in mind the dangers inherent in

the use of potassium thiocyanate and the possibility of fatality if the drug is used in the presence of renal impairment. Acute psychosis in the course of treatment should also be regarded as a danger signal.

SUMMARY

A case of acute toxic psychosis and death associated with potassium-thiocyanate treatment of hypertension is described, being the tenth case of this type to be reported in the literature.

MEDICAL PROGRESS

REGIONAL ANESTHESIA*

MORRIS J. NICHOLSON, M.D.†

BOSTON

IN THE current progress of regional anesthesia three new developments are outstanding. They are continuous caudal anesthesia for obstetrics, the subarachnoid injection of ammonium sulfate for the relief of intractable pain and refrigeration anesthesia (cryoanesthesia). However, because the anesthesiologist of today is interested in many things other than merely rendering patients insensible to pain during an operation, sections on new drugs, local anesthesia, spinal anesthesia, supportive treatment, complications and military anesthesia are included in this report.

CONTINUOUS CAUDAL ANESTHESIA

The idea of painless childbirth has been an enchanting one to anesthetists as well as to mothers since the introduction of chloroform. Continuous caudal anesthesia is the latest method holding forth this promise to appear on the anesthesia horizon. Manalan,¹ in August, 1940, introduced a technic that could have been but was not used for the continuous production of caudal anesthesia. He inserted a 13-gauge needle in the sacral hiatus and passed a No. 4 nylon ureteral catheter in through the needle, withdrawing the latter and leaving the catheter in place. After labor had progressed to the point that caudal anesthesia was needed, he injected 30 cc. of an anesthetic solution through the catheter into the sacral cavity and withdrew the catheter.

Hingson, Southworth and Edwards,²⁻⁴ impressed with the possibility for the use of the equipment described by Lemmon⁵ for continuous spinal anesthesia, adapted this apparatus (a malleable needle, tubing and syringe connected by Luer-Lok connections) for the production of continuous caudal anesthesia for obstetrics. The type of needle has been changed as dictated by their experience, as some of the original needles broke in situ. Adams and his co-workers⁶ have reported the use of a ureteral catheter by the method described by Manalan to obviate the possibility of breaking needles and to inject their agent through the catheter to produce continuous anesthesia. Several years after this method has been given a critical trial in in-

stitutions throughout the country, a worth-while evaluation of its place in obstetrics will be forthcoming. Any attempt at this stage of development to apply continuous caudal anesthesia routinely in all obstetric cases is apt to bring about some undesirable results. Southworth, Edwards and Hingson⁷ point out the possibilities of this method in certain types of general surgery, as well as in obstetrics.

RELIEF OF INTRACTABLE PAIN

Rovenstine and Wertheim⁸ make a plea for anesthetists to familiarize themselves with the various nerve blocks to provide pain relief for patients suffering from trigeminal, brachial-plexus and cervical-plexus neuralgia, sciatica, coccygodynia and shoulder pain. They advocate alcohol block of the sympathetics by the paravertebral route for angina pectoris and thrombophlebitis. Sensory-nerve block with alcohol for pain relief in inoperable carcinoma has been extremely worth while in their hands. These procedures are done only after medical treatment has failed to relieve pain or when surgical transection of sensory pathways is considered a grave hazard. Allen and Tuohy⁹ report that somatic pains can be successfully relieved in many cases by local anesthetization.

Bates and Judovich¹⁰ in an attempt to relieve intractable pain have administered 3000 injections of ammonium-salt preparations by the paravertebral route and by local infiltration. Starting with an extract of the pitcher plant (*Sarracenia purpurea*), the active principle of which they concluded was the ammonium ion, they now use ammonium sulfate. At present they inject it subarachnoidly in an attempt to control all types of intractable somatic pain. They state: "Intraspinal ammonium sulfate did not yield satisfactory results in the so-called 'pre-metastatic' phase of malignancy. The complaints of burning, urgency, tenesmus and other pains of this period were not relieved." At the time of injection, severe pain is experienced in the area supplied by nerves bathed by this solution. This can be eliminated, they state, by preceding the injection with 50 mg. of procaine hydrochloride, which provides a short period of spinal anesthesia.

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas Company, 1942. \$5.00).

*From the Department of Anesthesia, Lahey Clinic, Boston.

†Anesthetist, New England Baptist and New England Deaconess hospitals, Boston.

Hand¹¹ used ammonium sulfate subarachnoidly by the method described by Bates and Judovich in an attempt to relieve 48 patients of their intractable pain. Thirty-two of these patients had metastatic malignancy, and in 16 the treatment was successful. Six of 7 patients suffering from painful spinal-cord arachnoiditis had relief of pain. Four patients who had become addicted to morphine before treatment was instituted and 4 additional patients whose pain was finally thought to be on a functional basis received no relief. Hand thought that the major difficulty with this procedure was the inability to predict the outcome of the treatment before it was instituted, since he found it impossible to differentiate somatic pain as defined by Bates and Judovich.

Three minor complications usually accompany this treatment. First, 70 to 80 per cent of the patients experienced nausea and retching during the induction of anesthesia. This nausea could be relieved or attenuated by intravenous injections of 1/100 gr. of atropine sulfate. Secondly, 50 to 60 per cent experienced a post-spinal headache. Thirdly, 20 to 30 per cent were annoyed by varying degrees of paresthesias over the buttocks and sacrum.

REFRIGERATION (CRYOANESTHESIA)

In 1939, after long and careful study of the effects of resistance of peripheral tissue to asphyxia at various temperatures, Allen¹² suggested the possible usefulness of maintaining life processes at a reduced rate by lowering the temperature. Radical chilling of the body had previously been introduced by Fay¹³ for the cure of cancer, but he also described dramatic control of infections, including gas gangrene. True refrigeration anesthesia was first used for amputations of partially gangrenous extremities of patients in the older age group. When a tourniquet is applied and the extremity packed in ordinary chipped ice (without salt), the oxygen demands are reduced sufficiently (13 per cent for each degree centigrade) to prevent necrosis for many hours. The skin temperature falls to 2 to 4°C. and surgical anesthesia is complete within about two hours. From the anesthesia standpoint, this is thought to be an entirely new principle, namely anesthesia of protoplasm, in contrast to all former methods, which produce only anesthesia of nerves.¹⁴

Theoretically, one might expect that the tourniquet and refrigeration would increase the dangers of postoperative slough. Practically, it has been found that the factors of safety in this respect are quite adequate even in the presence of arterial disease. One report of 58 amputations done with

this type of anesthesia gave the following as its benefits: ease and quickness of operation, absence of pain both before and after operation, inhibition of infection, conservation of poorly nourished tissues, control of edema, promotion of drainage when necessary, probable reduction of thrombotic and embolic dangers and, pre-eminently, the avoidance of shock.^{15, 16}

McElvenny¹⁷ used intensive refrigeration without a tourniquet to control pain, to prevent infection and to overcome shock in a patient who had bilateral traumatic leg amputations.

Refrigeration anesthesia seems to offer advantages for nearly all cases of severe wounds of the extremities. Prevention and treatment of shock may be sufficient indications; surgical anesthesia is a valuable by-product. It has been advocated for use in combat areas by military surgeons to relieve the suffering and blood loss from periodic loosening of an emergency tourniquet.¹⁸

NEW DRUGS

In 1939, Eisleb and Schaumann¹⁹ introduced a new synthetic phenyl-piperidine derivative, Demerol (1 methyl, 4 phenyl-piperidine, 4 carboxylic acid ethyl hydrochloride), which was found to possess properties similar to those of atropine and morphine. Since then numerous European investigators have attested to the drug's usefulness in the therapy of pain.²⁰ Batterman²¹⁻²³ studied the analgesic effectiveness, potency and safety of Demerol, and concluded that it could be used for patients who would ordinarily require opiates. He found the drug similar to morphine in its analgesic action and approaching it in effectiveness, but with less depression of the central nervous system. Unlike morphine, depression of the respiratory rate and urinary retention are rare following therapeutic doses. The size of the pupils and the pupillary reflexes are not affected, and in recumbent subjects there is no appreciable alteration in blood pressure, ventricular rate, electrocardiogram or basal metabolic rate.

Climenko and Berg²⁴ in a study of the influence of Demerol on the contraction of the ureter concluded that it inhibits the amplitude of contraction and diminishes the tonus of the ureter.

Rovenstine and Batterman²⁵ studied this drug to evaluate its effectiveness as a preanesthetic agent in man and to determine the differences between its action and that of morphine. They concluded:

[Demerol] will provide psychic sedation not surpassed by morphine; will not depress respiration or other vital functions to the same degree as will comparable amounts of morphine; will facilitate induction of anesthesia as does morphine; is more effective in

drying secretions than morphine; has fewer unfavorable side effects, such as nausea and vertigo, than morphine; and will reduce the amount of anesthetic agent required to produce the optimal degree of narcosis to the extent that can be obtained with morphine.

In 1937, the synthesis of monocaine hydrochloride (mono-isobutyl-aminoethyl-para-aminobenzoate hydrochloride), an isomer of procaine, was reported by Goldberg and Whitmore,²⁵ who claimed that it was a good local anesthetic with pressor action and synergistic with epinephrine. They also stated that a 1 per cent concentration could be used without the addition of epinephrine. After extensive investigation designed to test the local anesthetic efficiency of monocaine, its possible direct vasoconstrictor power, its local and systemic toxicity and its effects on vital function, Schamp, Schamp and Tainter²⁶ reported the following:

These results taken together indicate that the local anesthetic efficiency of monocaine is similar to that of procaine quantitatively and qualitatively, as is also the systemic toxicity, except for a greater cardiovascular paralyzing action of monocaine. They also fail to substantiate current claims that monocaine is a pressor agent, or that it potentiates the action of epinephrine. Since monocaine is definitely more irritating to tissues than procaine, it lacks the advantages which would justify its selection over procaine as a local anesthetic for injection purposes.

The formic acid salt, monocaine formate, which is soluble in any dilution needed clinically, was used by Burdick and Rovenstine²⁷ for a clinical study of the drug as a spinal anesthetic agent. They used technics for administration commonly employed for spinal anesthesia with procaine, dissolving the monocaine formate crystals in the spinal fluid to make concentrations of 2.5, 5.0, 7.5 and 10.0 per cent. Diffusion of monocaine was found to differ from that of procaine in the spinal fluid, and the level of sensory anesthesia sometimes continued to extend cephalad for as long as thirty minutes. "With the amounts used, 50 to 150 mg. in 5 per cent concentration in spinal fluid, the results observed during anesthesia and post-operatively indicate that complications are no more severe and of lower incidence than might be expected from procaine." In conclusion, they expressed the belief that monocaine is a safe, useful agent for spinal anesthesia when given in low concentration and in small or moderate doses.

LOCAL ANESTHESIA

Beutner and Calesnick²⁸ carried out experimental research to find the physiologic and chemical properties possessed by many of the widely used

local anesthetics. They concluded that efficient local anesthetic agents have so far been obtained only as ester compounds of benzoic acid, amino-benzoic acid or some related substituted benzoic acid (Nupercaine, quinolin carbonic acid, used in one instance). These acids are combined with some amino alcohol or a related compound (for Nupercaine, one having a diamino radical) that supplies the basic property. The ester-like loose combination between the acid and the amino alcohol is the essential indispensable characteristic.

Physiologically all efficient local anesthetics have been found to be convulsants and stimulants of the cerebral cortex, the convulsive power being approximately parallel with the efficiency of the local anesthetic agent.

Apparently it is more than a casual coincidence that all efficient local anesthetics are convulsants. They must possess a marked affinity to the nerve cells in order to depress selectively the terminal nerve fibers without injuring the cells.

Mousel,²⁹ Tuohy,³⁰ Adams³¹ and Seldon and Lundy^{32, 33} have recently published timely and worth-while papers covering the commoner regional nerve-block technics for all parts of the body. One finds a crystallization of valuable clinical experience in these writings that comes only after years of experience. These articles should be read by all anesthetists interested in the proper application of regional anesthesia in modern anesthesiology.

Much interest has been shown of late in the use of local infiltration and regional block anesthesia for obstetrics.³⁴⁻³⁷

SPINAL ANESTHESIA

Goldberg, Koster and Warshaw³⁸ write as follows:

By means of new chemical technics it is shown that procaine within the subarachnoid space remains essentially unchanged. The fall in concentration of procaine, which is responsible for the wearing off of spinal anesthesia, is due to vascular absorption. Once in the blood stream procaine is rapidly hydrolyzed (detoxified) by an enzyme. . . . At no time is there any appreciable trace of procaine in the blood; hence, the cause of various "toxic" effects which have been attributed to a procainemia must be sought elsewhere. . . . Nearly all the injected procaine (90 per cent on the average) is excreted in the urine, but only in the form of products of detoxication.

In a recent study of spinal anesthesia in normal, unoperated man, Smith, Rovenstine and their collaborators³⁹ have shown that anesthetic denervation does not produce renal hyperemia. Smith⁴⁰ has more recently reaffirmed this conclusion after a more complete review of the literature. In the first paper the authors suggested that the arteriolar

bed generally—apart from the skin—possesses considerably more autonomy than is usually attributed to it. They believe that blood pressure may change very little during high spinal anesthesia in normal, unoperated man. For the most part, such decrease as was observed in these unoperated patients was a result of the decrease in the stroke volume of the heart, which they attributed to a decrease in venous pressure.

The extreme falls in blood pressure observed during high spinal anesthesia are believed by Papper, Bradley and Rovenstine^{41, 42} to be the result of decreased venous pressure (and hence a decreased cardiac output) following opening of the abdomen and the attendant operative procedures inflicted in the face of vasomotor paralysis and loss of vasomotor defense. Trauma, hemorrhage, anoxia, the weight of metal and other items upon the abdomen, the pressure of packs between the viscera, the position of the patient, malaise, fever and other complicating factors may contribute to the progressive reduction in venous pressure and the ultimate embarrassment of the circulation.

There seems to be a trend toward wider clinical application of spinal anesthesia by anesthetists in general.⁴³ This appears to be due to increasing confidence in the ability of vasomotor drugs, plus intravenous fluids (saline and glucose solutions, plasma and blood) to combat the hypotension often associated with spinal anesthesia. In addition, certain refinements in technic for spinal anesthesia have given the anesthetist more control over the distribution of the drug in the subarachnoid space.^{44, 45}

Fractional (continuous) spinal anesthesia is gaining in favor and seems to have answered a real need where ensured relaxation is needed over long periods for difficult abdominal or orthopedic operations.⁴⁶⁻⁴⁹ To date there has been a lack of uniformity of opinion concerning the best anesthetic agent to use by this method.

SUPPORTIVE TREATMENT

Every effort should be made through the use of supportive treatment to prevent the onset of shock or to institute treatment before the condition has progressed irrevocably. Certain tests may detect shock during its earlier stages when significant changes are noted in the hematocrit, the specific gravity of the plasma and whole blood and the plasma protein level.⁵⁰ The benefit of whole blood and plasma transfusion to the patient in shock is beyond question. Elman⁵¹ has shown that a solution of hydrolyzed protein containing amino acids and polypeptides exerts a definite therapeutic effect, as evidenced by prolongation of the survival time, an increase in the amount of

hemorrhage that could be sustained and a higher level of blood pressure as compared with that in controls in whom dextrose alone was used or in whom there was no replacement.

Because of the part that tissue anoxia must play in the vicious cycle of shock, it is interesting to note the favorable effect of administering high oxygen concentrations reported in two recent papers.^{52, 53} Others⁵⁴ report that the course of events in hemorrhagic shock is in no way altered when venous anoxemia is prevented by administering oxygen at high pressure.

Beecher, McCarrell and Evans⁵⁵ have confirmed the observations of Seeley, Essex and Mann⁵⁶ that shock produced in dogs by exposure and manipulation of the intestine is slower to appear when barbiturate (sodium amytal) anesthesia is used than when ether anesthesia is employed. However, they found no significant delay in the onset of shock produced by hemorrhage when barbiturate anesthesia was used. Their observations together with those of Parsons and Phemister⁵⁷ and Blalock,⁵⁸ who found similar effects under barbiturate and ether anesthesia when shock was produced by muscle trauma, indicate that barbiturate as compared with ether anesthesia is not useful in delaying all types of shock.

Studies have been made by Seligman and Fine,^{59, 60} using a radioactive plasma protein, to test the prevailing opinion that an increased permeability of the capillaries exists in shock and that a subsequent loss of plasma into the tissues ensues, so that the effective circulating-blood volume falls to a level incompatible with life. They found that, whereas the integrity of the capillaries may be impaired in the latent shock phase, there is no evidence of the significant loss of plasma into the tissues in untreated fatal shock following hemorrhage.

Infusion of blood and other fluids through the bone marrow, as advocated by Tocantins,^{61, 62} gives another route by which large amounts may be administered. This method is particularly applicable in pediatrics, since transfusions to children under the age of two years are difficult to give by vein. It is also important in adult patients whose bodies are widely burned or whose veins are thrombosed. These intramedullary infusions are injected into the bone marrow of the manubrium sterni in adults and into the tibia or femur in infants. Doud and Tysell⁶³ were able to inject 9025 cc. of blood and 13,155 cc. of fluid into the sternal marrow of an adult by this method over a ten-day period.

COMPLICATIONS

The possibility that gangrene of a toe or finger will result from a nerve block with procaine

epinephrine solution is emphasized in all standard texts on regional anesthesia. The literature reports two such happenings, one involving a finger and the other a toe.^{64, 65}

At some time every surgical team will be called on to face the serious responsibility of a sudden cardiac arrest in the operating room. One such case, which occurred while the patient was receiving an inhalation anesthetic for a left lower lobectomy because of bronchiectasis, is reported in detail by Adams and Hand.⁶⁶ The probable cause of cardiac arrest, with treatment instituted that after twenty minutes resulted in a successful outcome, is given.

I was faced with a sudden cardiac arrest in a patient under spinal anesthesia during the last year. Approximately twenty-five minutes after the induction of anesthesia, while the surgeon was carrying out a high abdominal exploration, the pulse and blood pressure suddenly could not be obtained and respiration ceased. Vigorous artificial respiration carried on through an endotracheal tube with oxygen from a gas machine was started immediately, as was cardiac massage through the diaphragm, by the surgeon. One cubic centimeter of epinephrine was injected into the heart muscle, and the arrest was overcome in approximately three to four minutes after the pulse had disappeared. The patient made an uneventful recovery except for the loss of memory for a period of about two days.

Judging from the above experiences and those of Beck,⁶⁷ it seems reasonable to make every effort to save the lives of these patients. Prompt, adequate and properly selected methods of stimulating the return of cardiac function and the maintenance of adequate cerebral oxygenation are essential. Artificial respiration must be instituted with a gas machine after an intratracheal tube is inserted. Cardiac massage must be promptly started either through the chest or the left diaphragm. If the operation is not being carried on in the chest or abdomen, a transthoracic approach is quickly made. Small doses of epinephrine—0.5 to 1.0 cc.—injected into the cardiac muscle seem to be almost a necessity.

The surgical importance of atelectasis is obvious. It may complicate convalescence from any operation, and it is probably the most commonly encountered pulmonary complication after abdominal operation. Schmidt, Mousel and Harrington⁶⁸ present an interesting paper dealing with a series of 84 selected cases of postoperative atelectasis. Fifty-eight of the patients were men and 26 were women. The average age of both men and women was fifty years. There were no preoperative roentgenographic signs by which the likeli-

hood of postoperative atelectasis could have been foretold. In 52 of the cases the operations were on the biliary tract or stomach, in 9 cases on the colon, and in 8 cases on the kidney or its surrounding tissues; the number of cases representing other operations probably was not significant. In all cases in which atelectasis followed operation on the kidney, the lung affected was the one corresponding to the side on which the patient was lying. If treatment was begun within forty-eight hours after the complication occurred, the results were excellent. If the complication existed for seventy-two hours or longer before treatment was begun, recovery was usually slower, since secondary pneumonia had usually developed.

MILITARY ANESTHESIA

In an excellent article that brings the history of anesthesia in war surgery up to date since ether was discovered in 1842, Pender and Lundy⁶⁹ concluded with these predictions about anesthesia in the present war:

Chloroform will be the reserve anesthetic agent for use under adverse circumstances.

Ether will form the foundation anesthetic agent when other agents are not satisfactory.

Local anesthesia will be either used alone or supplemented whenever possible.

Nitrous oxide and oxygen will be most useful for simple induction and for short operations.

Spinal anesthesia administered by experienced hands will be safer than ever before for operations performed below the diaphragm.

Quick-acting barbiturates administered intravenously will be used more often than any other type of anesthetic agent.

Rectal anesthesia will be used seldom.

Cyclopropane will be unequaled for anesthetizing many patients in base hospitals.

The intratracheal method will be almost the routine manner of administration of the volatile anesthetic agent.

Martin⁷⁰ believes that the advances in anesthesiology since World War I are reflected in its inclusion in the organization of hospitals of the United States Army.⁷¹ Anesthesiology, for the first time, was set aside as a section by itself on the Surgical Service of the Tilton General Hospital, Fort Dix, New Jersey, for instruction of medical officers in the fundamental principles of anesthesiology.⁷²

Several anesthetists have related their experiences in England⁷³ and the Middle East⁷⁴ at large general hospitals. Much of the work was of the same general character as that seen in any large civilian hospital, except for the emphasis on traumatic cases. Inhalation anesthesia by the intratracheal route seems to have been most popular. Intravenous Pentothal Sodium was used widely for minor surgery, spinal anesthesia was seldom

used, and local anesthesia was used little if at all. Because the problems of anesthesia in a small portable hospital immediately behind the front lines are so entirely different from those encountered at a base hospital, inclusion in this article of part of a recent communication seems timely. Swinton,⁷⁵ commanding officer of a small portable hospital that functioned for months in New Guinea, writes as follows about anesthesia.

In about 500 operations that I saw performed practically in the front lines, Pentothal Sodium was used almost routinely. These boys come in tired out, dirty and already heavily narcotized at the aid stations. All of them are frightened, and most of them are in more or less shock. We use plasma by the gallon. Pentothal served 95 per cent of all purposes. Spinal anesthesia can be used in a few of the abdominal cases if the shock can be quickly and safely controlled, but I stuck to ether in these cases. It is hard work, though, when one is spoiled by the relaxation of spinal anesthesia. Pentothal is easy to carry, easy to prepare, not bulky, and almost foolproof in any operation requiring up to forty-five minutes to one hour. Most front line surgery can be done very rapidly and in less time than in civilian practice. No aftereffects and quick recovery so that evacuation is not interfered with are important points in this work. One patient in this group died, and Pentothal should never have been given to him—just plain stupid selection of an anesthetic agent.

CASE 29311

PRESENTATION OF CASE

First admission. A fifty-two year-old meat dealer entered the hospital because of abdominal distress and jaundice.

He was well until three weeks before admission when he developed attacks of severe abdominal and substernal distress after eating that lasted for several hours and were often associated with anorexia. At the same time a steady aching discomfort developed between the shoulder blades and persisted to the time of admission. During one attack of distress he vomited bile stained food without much relief. Nausea and anorexia developed and he became constipated. Four days prior to admission a physician told him that he was jaundiced and prescribed a bland fat-free diet, which relieved the epigastric distress and anorexia. The jaundice, however, deepened, the urine became dark, and the stools clay colored. There were no chills or fever. The patient denied the use of alcohol or drugs. During his illness he was said to have lost a great deal of weight.

The family and past histories were noncontributory.

Physical examination disclosed a well-developed, moderately jaundiced man in no apparent discomfort. The scleras were deeply jaundiced. The heart and lungs were normal. There was a sense of fullness in the right upper quadrant of the abdomen but no masses were felt, and no tenderness or rigidity was elicited.

The blood pressure was 120 systolic, 70 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a hemoglobin of 128 gm and a white cell count of 7800, with 69 per cent neutrophils. The urine showed a + test for bile. A blood Hinton test was negative. The serum protein was 68 gm. per 100 cc., the phosphorus 3.3 mg., the phosphatase 170 Bodansky units and the bilirubin 3.9 mg. direct and 6.2 mg indirect. The prothrombin time was 18 seconds (normal, 20 seconds). The stool was greenish brown and repeatedly guaiac negative.

*On leave of absence

A flat plate of the abdomen revealed a liver that was slightly smaller than normal. The spleen was at the upper limits of normal. No definite stones were seen. On the sixth hospital day an exploratory laparotomy was done, with a preoperative diagnosis of "obstructive jaundice, probably due to a stone in the common duct." At operation the gall bladder was moderately distended. There was no evidence of metastatic disease of the liver. The pancreas was about three times normal size, nodular and irregular. There was no evidence of fat necrosis. The common duct was about twice normal size and no stones were found. A cholecystgastrostomy was done. A pancreatic biopsy was reported as chronic pancreatitis with fibrosis.

Following operation the jaundice cleared, the urine became pale and the stools brown. Between the eleventh and eighteenth postoperative days he was given x-ray treatment (1200 r) over the pancreas. The patient was discharged on the twenty-fourth hospital day.

Second admission (fourteen months later) The patient re-entered the hospital because of the onset of dark urine, clay-colored stools and a nagging, sometimes painful sensation in the back between the shoulder blades. The patient had been fairly well and had been free from jaundice, bristly skin and malaise until one week prior to entry. Three days prior to entry jaundice appeared. There were no chills, fever, nausea or vomiting.

Physical examination was similar to that of the first admission. The liver edge was palpable two fingerbreadths below the right costal border.

The temperature, pulse and respirations were normal. Examination of the blood revealed a red-cell count of 5,250,000, with a hemoglobin of 15.1 gm, and a white-cell count of 8400, with 57 per cent neutrophils. The urine was normal. The serum bilirubin was 3.4 mg per 100 cc direct and 4.35 mg indirect. The stool was light tan, and guaiac negative. Gastric analysis failed to reveal free hydrochloric acid, either before or after a test meal. The stomach content was guaiac negative.

An x-ray film of the chest was negative. Because the patient desired to return home to consider operation, he was discharged, unimproved, on the seventh hospital day.

Final admission (six weeks later) After discharge he was awakened several times at night by mild epigastric discomfort that was partly relieved by warm water or milk. Four weeks prior to admission his stools became pale, and the urine dark brown. Three weeks prior to admission the jaundice deepened and generalized pruritus developed. His appetite decreased, but he had no nausea, vomiting, hematemesis or melena. Two

weeks prior to admission he developed diarrhea and often had two to seven movements a day for three or four days, but this was relieved by tincture of belladonna. The liver was felt 2 cm. below the costal margin in the right anterior axillary line, 6.5 cm. below in the midclavicular line, 8 cm. below the xiphoid, and 6 cm. below the left costal margin. The spleen was neither palpable nor percussable. There was no shifting dullness or fluid wave.

The temperature, pulse and respirations were normal.

The urine showed a + test for albumin, a ++++ test for bile and no urobilinogen. The serum bilirubin was 10.4 mg. per 100 cc. direct and 14.8 mg. indirect. Five days later it was 12.3 mg. direct and 17.5 mg. indirect. The prothrombin time was 23 seconds (normal, 18 seconds). The stool was gray, guaiac negative and contained neutral fat.

The jaundice increased, and the patient complained of increased urinary frequency and vague abdominal discomfort. After preparation with saline-glucose infusions and water-soluble vitamin K, an exploratory laparotomy was performed on the eleventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: The history of the first admission without any question indicates that we are dealing with a patient with obstructive jaundice. There are a number of conditions that can produce obstructive jaundice, the commonest of which, of course, is cholelithiasis with a stone in the common duct or an extrahepatic lesion producing pressure on the common duct, such as carcinoma of the head of the pancreas or carcinoma of the papilla of Vater. Carcinoma of the biliary passages can also produce obstructive jaundice, but it is my opinion that this lesion produces obstructive jaundice of complete degree and of a much more rapid nature than this man developed. Another cause of jaundice that one ought to consider is cirrhosis of the liver. This is usually not complete obstruction, however, and associated with it, one usually finds a large spleen. We have evidence here by x-ray and physical examination that the spleen was relatively small or normal in size. Another condition that one encounters is pancreatitis, which sometimes produces a sclerosing type of lesion that obstructs the common duct as it passes behind the duodenum.

I do not believe there is anything in the laboratory findings of diagnostic importance. It is interesting that the phosphatase was elevated, which is the usual finding in obstructive jaundice. The

bilirubin was elevated but not markedly, 3.9 mg per 100 cc. direct, with a total of 6.2 mg., which indicates that the patient had obstructive jaundice rather than jaundice due to blood destruction. The prothrombin time was essentially normal, so that he did not have a hemorrhagic diathesis.

At the operation we learn that the gall bladder was moderately distended; no stones were found, and the pancreas was enlarged. These observations confirm Courvoisier's law, namely, that a dilated gall bladder in the presence of jaundice usually means extrahepatic biliary obstruction rather than obstruction due to stone. It is of interest that a biopsy of the head of the pancreas was reported "chronic pancreatitis with fibrosis." Biopsies of the head of the pancreas are, I believe, notoriously inaccurate because of the fact that in carcinoma of the pancreas one may have obstruction of the pancreatic duct with a good deal of thickening and fibrosis of the pancreas, and what one thinks is a malignant lesion is really secondary fibrosis from obstruction of the pancreatic duct by carcinoma. So far as the story at the first admission is concerned one must decide whether one is dealing with carcinoma of the head of the pancreas or pancreatitis due to unknown causes, both of which produce obstructive jaundice. The fact that the patient received 1200 r of x-ray therapy makes me inclined to think that at that time the diagnosis of cancer of the pancreas was favored over that of pancreatitis.

At the second admission, fourteen months later, the patient re-entered because of the onset of dark urine, clay-colored stools and a painful sensation between the shoulder blades. He had been relieved temporarily by the cholecystgastrostomy, which apparently functioned very well for a little over a year, when his symptoms began to return.

After a period of six weeks from the time of the second admission the patient returned with evidence of marked obstructive jaundice, which had resulted in a large liver. It is interesting that he developed diarrhea of from two to seven movements a day for three or four days. If he had pancreatic obstruction, I am surprised that that came on so late. If he had had pancreatic-duct obstruction without any external pancreatic secretion going into the intestinal tract, I should have thought that he would have had steatorrhea earlier. His condition was getting worse, as indicated by the serum bilirubin, which jumped from a total of 14.8 to 17.5 mg. in five days' observation. I believe the diagnosis still lies between cancer of the head of the pancreas and chronic pancreatitis.

In favor of its being carcinoma of the head of the pancreas is the fact that this is the commonest

lesion that produces obstructive jaundice in cases in which the pancreas is involved. I have seen one patient* who had had cholecystgastrostomy who lived for three years before he finally died of carcinoma of the pancreas; we wondered, until we finally did ascertain what his trouble was at autopsy, whether we were not dealing with chronic pancreatitis. The case we are discussing did not go quite that long, only fourteen months. Another interesting point is, Why did this man do so well for over a year and then develop obstructive jaundice? Certainly the cholecystgastrostomy worked well at first, and why it did not continue to work well seems a little strange. The fact that it did not work continuously and relieve the jaundice permanently suggests that one was dealing with a malignant lesion and that the malignant disease had eventually involved the cholecystgastrostomy. We have no evidence, however, so far as physical examination goes, that the patient had metastatic disease involving the abdominal cavity, such as a nodular liver or other masses.

On the other hand if one assumes this is pancreatitis, then one has to postulate that for some reason or other the cholecystgastrostomy failed to function after a period of time. I think we have observed on occasions that cholecystgastrostomies and choledochostomies do close off spontaneously if the normal biliary circulation through the ampulla of Vater is re-established, and I think that is a possibility in this case. If so, it would favor the diagnosis of pancreatitis. It seems to me on the evidence presented here, however, that the more likely diagnosis is carcinoma of the pancreas with extension and finally obstruction of the short-circuiting operation that was performed.

DR. BENJAMIN CASTLEMAN: Dr. Allen, will you tell us your impression of the case?

DR. ARTHUR W. ALLEN: Dr. Jones and Dr. Benedict are both interested in this patient. Dr. Linton's reasoning about the first admission was I think in accordance with our own. We thought it was possible that, with the biopsy of the pancreas, we did not obtain a piece of the true lesion, although Dr. Mallory made sections of it and felt quite certain that it was an inflammatory process. Dr. Jones has just reminded me that the process involved the entire pancreas and was not localized to the head, as we nearly always see it in cases of carcinoma of the pancreas with jaundice.

Dr. Linton wondered why the patient had radiation afterward and thought that might help him in his diagnosis of malignant disease. The reason he had that treatment was based on the idea of

Morton,* of Rochester, New York, who has suggested that, since the pancreas is so much like the parotid gland in its structure and since radiation works so well in acute parotitis, mild radiation in pancreatitis may be of value. So we gave a small amount of x-ray therapy, 1200 r, divided in four doses. He recovered so completely that we believed that he really did have an inflammatory rather than a malignant lesion. Dr. Jones and I even considered the possibility of disconnecting the cholecystgastrostomy for fear of an ascending cholangitis. When the patient came in to Dr. Jones for a check-up six months later, he found evidence of a good deal of liver damage, which he will tell you about, and the question of reoperation was dropped, until he became jaundiced again and began to have symptoms. We reasoned very much as Dr. Linton did; that is, we might have made a mistake in our original diagnosis and the patient might have had a respite from carcinoma during this period. Dr. Benedict therefore performed a peritoneoscopy and found a swollen liver without any nodules; a biopsy showed obstructive jaundice.

We then explored the patient, after adequate preparation. He had 100 per cent dye retention in the liver. At operation, we found a small, hard pancreas, which was possibly one fourth the size that it was originally, and another biopsy specimen, a generous one, examined by Dr. Castleman showed fibrosis of all the pancreatic elements with nothing but islet cells left in the gland. We therefore reasoned that he had had inflammatory disease from the start and that the reason the cholecystgastrostomy had closed was exactly as Dr. Linton suggested—during a period of his early convalescence the portion of the duct that went through the pancreas was released, the duct functioned again and therefore nature had closed the artificial opening. We further reasoned that, at this time, a permanent arrangement for the passage of bile into the intestine should be made. We therefore anastomosed the cut end of the jejunum to the fundus of the gall bladder in an isoperistaltic direction, re-anastomosing the other end of the jejunum to the side of the gut after the method of Roux. The procedure was well planned and there were no difficulties, but, as Dr. Castleman will tell you, it was too much for a man who was as sick as this one. The patient died two days later with what we believed to be liver failure, quite like the kind of death we used to see in patients who had their hepatic arteries tied accidentally.

*Morton, J. J., and Widrer, S. Diagnosis and treatment of acute pancreatitis. *Ann. Surg.* 111: 851-863, 1940.

DR. CHESTER M. JONES: There are one or two other points of interest. I saw this patient a year after the first operation and followed him closely. He had no symptoms except diarrhea. He recovered from his jaundice, about a month after the first operation there being no trace of it. At that time the liver was two fingerbreadths below the costal margin. In other words it had diminished in size appreciably. Six months after operation he was feeling better and had no jaundice, the liver was just barely palpable, the bilirubin was 0.4 mg. per 100 cc., a perfectly normal figure, and the dye retention was 10 per cent. That made me wonder whether he had some permanent liver damage.

Six months later he had no jaundice, but the liver was two fingerbreadths below the costal margin, definitely larger. Because of the discrepancy we checked the laboratory findings and found that he had 60-per-cent dye retention and increased blood bilirubin. He remained free of jaundice until three or four weeks before he finally was operated on, and then, rather suddenly, clinical jaundice recurred. At that time the dye retention was 100 per cent. Dr. Allen and I thought that regardless of the cause of the block there must have been a lot of liver damage, which was explainable on the basis either of diffuse hepatic involvement by carcinoma, which was unlikely, or a diffuse process in the nature of a biliary cirrhosis. The biopsy specimen that Dr. Benedict took had the microscopic appearance of biliary cirrhosis. In other words, the biopsy fitted the clinical picture, but it was still impossible to tell what was the underlying cause.

DR. LINTON: I still do not see why the patient became jaundiced so suddenly at the end.

DR. JONES: I think what happened was that he had a fairly active low-grade inflammatory process involving the pancreas and probably the liver itself. At any rate at a point in the course of the illness the cholecystgastrostomy closed over completely. When Dr. Allen operated he could not get a probe into the opening of the gastrostomy. Is that not correct, Dr. Allen?

DR. ALLEN: Yes; there was no opening into the stomach.

CLINICAL DIAGNOSIS

Obstructive jaundice.

DR. LINTON'S DIAGNOSIS

Carcinoma of the pancreas?
Chronic pancreatitis?

ANATOMICAL DIAGNOSES

Chronic pancreatitis, severe, with stenosis of common bile duct.
Obstructive biliary cirrhosis of liver.
Cholelithiasis.
Choledocholithiasis.
Ascites.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The biopsy showed that the pancreas was, as had been described at the second operation, very small and fibrotic. The sections from the autopsy material confirmed the biopsy sections, showing a diffuse interacinar and perhaps interlobular type of chronic fibrous pancreatitis. There was atrophy of the acinar cells and replacement of much of the parenchyma by fibrosis and lymphocytic infiltration so that only the islet cells and ducts remained. This was much severer in the region of the head of the pancreas but was also present throughout the organ. The opening of the bile duct at the ampulla was tiny, and the common bile duct above was markedly dilated, about 3 cm. in circumference. This stenosis had undoubtedly been produced by the surrounding fibrous pancreatitis. There was no carcinoma. In the common duct, as well as in the gall bladder, we found muddy material and a few small stones (0.5 to 1 mm. in diameter), which was evidence that the infection was still going on in the biliary tract.

The liver showed widespread fibrosis of the biliary type, with proliferation of the bile ducts characteristic of fairly long-standing obstructive jaundice. There were 2 liters of bile-stained fluid in the abdominal cavity. The anastomoses were intact, and I believe that death was due to liver failure. I find it hard to conceive that the bile duct was ever patent enough to allow for a closure of the anastomosis because of disuse. I think he was getting all his bile through the anastomosis until it closed. Why, I do not know.

DR. ALLEN: My reasoning about it is that at the time of the first operation the pancreas was tremendously swollen, four times the normal size, from the inflammatory process, that the edema around the pancreatic portion of the duct produced the jaundice and then when the anastomosis was established the inflammation in the pancreas receded enough afterward to allow a temporary passageway for the bile to go through its natural course. During the temporary normal passageway, the anastomosis shut down. The duct did not completely close off—again due to the fibrosis—until one of these 1-mm. stones got down into

the narrow channel. That probably explains the question Dr. Linton asked about the suddenness of the final jaundice. As a matter of fact it took two or three weeks for it to become complete.

DR. CASTLEMAN: I do not believe that the bile duct would open when the pancreas became scarred; in fact this might tend to close it more completely.

DR. ALLEN: We have had many cases of jaundice associated with pancreatitis that have completely cleared up. I have seen only one previous case of complete fibrosis of the pancreatic portion of the bile duct. It may happen quite frequently, but that is the only other one I have seen. In that patient the pancreatitis was secondary to a penetrating duodenal ulcer.

DR. CASTLEMAN: This is the first true case of widespread chronic pancreatitis that I have ever seen. Mild degrees of focal chronic pancreatitis are not uncommon autopsy findings, but this severe form is distinctly unusual.

DR. LINTON: The original obstruction could have been due to edema. Fibrosis would take months.

DR. ALLEN: Yes; "edema" is the word for the early episode, and "fibrosis" for the final one.

DR. JONES: Furthermore, the patient had a slight amount of bile going through until the day of operation. X-ray films taken three weeks before failed to show barium going into the gall bladder, which it will do if the stoma is patent.

DR. ALLEN: That is correct. At the second admission roentgenograms showed no passage of barium from the stomach to the gall bladder.

DR. JONES: Dr. Allen and I discussed this case after operation. If we were confronted with a situation like this, where the liver was badly damaged, it would be worth considering a two-stage operation, simply relieving the block for the moment with drainage and doing the complete operation later. This is all in retrospect, but I think it should be mentioned.

DR. ALLEN: I have disliked doing two-stage operations for this type of obstructive jaundice because we rarely succeed in getting to the second stage. Sudden decompression of the liver has caused the patient to continue his decline. Possibly we should have been smart enough to have thought of operation when the dye retention rose to 60 per cent. We may never see another patient like this. It is an unusual case.

DR. LINTON: I wonder why you did not do the Roux type of operation rather than cholecystgastrostomy at the first operation.

DR. ALLEN: I expected this to be a temporary affair, and planned to disconnect it after the patient had recovered from the pancreatitis. I did not suppose he would develop fibrosis.

CASE 29312

PRESENTATION OF CASE

First admission. A seventy-nine-year-old Italian laborer entered the hospital because of a chronic ulcer of the right elbow occurring in the scar of an old burn.

Approximately forty years prior to admission the patient burned both elbows severely. These healed slowly with a great deal of scarring but without limitation of joint motion. Approximately one year prior to admission the scar about the right elbow ulcerated, often bled a great deal and never completely healed despite local treatment.

The family and past histories were noncontributory.

Physical examination disclosed a fairly well-preserved old man who seemed apprehensive. The heart, lungs and abdomen were normal. On the dorsal aspect of the left elbow over an area approximately 5 by 4 cm., involving the lower end of the upper arm and an equal area of the lower arm, were irregular scars traversed with many firm crusted ridges. The involved area of the right elbow measured approximately 14 by 12 cm. and was almost symmetrical in position to that of the left arm. In the center was a shallow ulcer, 12 by 8 cm., covered by shreds of necrotic tissue, fresh blood and greenish-yellow purulent exudate. There was almost no granulation tissue.

The blood pressure was 148 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red cell count of 4,440,000, with a hemoglobin of 84 per cent, and a white-cell count of 8200. The urine was normal. A blood Hinton test was negative.

X-ray films of the right elbow showed a large area of bone destruction from the upper one third of the shaft of the ulna with some soft-tissue swelling. There was no evidence of new-bone formation. There was a pathologic fracture through the area of destruction. A chest roentgenogram showed clear lung fields. There were several old fractured ribs on the right side. Following a report of epidermoid carcinoma, Grade 2, on a biopsy specimen from the edge of the ulcer of the right elbow, the right arm was amputated at the junction of the middle and lower thirds of the humerus. Dissection of the amputated limb showed extension of the neoplastic tissue from the base of the tumor into the subjacent proximal end of the ulna, with pathologic fracture 4 cm. from the proximal articular surface. Because of the severe local infections, the patient received a preoperative course of sulfadiazine. He was discharged on the eighteenth hospital day.

DR. CHESTER M. JONES: There are one or two other points of interest. I saw this patient a year after the first operation and followed him closely. He had no symptoms except diarrhea. He recovered from his jaundice, about a month after the first operation there being no trace of it. At that time the liver was two fingerbreadths below the costal margin. In other words it had diminished in size appreciably. Six months after operation he was feeling better and had no jaundice, the liver was just barely palpable, the bilirubin was 0.4 mg. per 100 cc., a perfectly normal figure, and the dye retention was 10 per cent. That made me wonder whether he had some permanent liver damage.

Six months later he had no jaundice, but the liver was two fingerbreadths below the costal margin, definitely larger. Because of the discrepancy we checked the laboratory findings and found that he had 60-per-cent dye retention and increased blood bilirubin. He remained free of jaundice until three or four weeks before he finally was operated on, and then, rather suddenly, clinical jaundice recurred. At that time the dye retention was 100 per cent. Dr. Allen and I thought that regardless of the cause of the block there must have been a lot of liver damage, which was explainable on the basis either of diffuse hepatic involvement by carcinoma, which was unlikely, or a diffuse process in the nature of a biliary cirrhosis. The biopsy specimen that Dr. Benedict took had the microscopic appearance of biliary cirrhosis. In other words, the biopsy fitted the clinical picture, but it was still impossible to tell what was the underlying cause.

DR. LINTON: I still do not see why the patient became jaundiced so suddenly at the end.

DR. JONES: I think what happened was that he had a fairly active low-grade inflammatory process involving the pancreas and probably the liver itself. At any rate at a point in the course of the illness the cholecystgastrostomy closed over completely. When Dr. Allen operated he could not get a probe into the opening of the gastrostomy. Is that not correct, Dr. Allen?

DR. ALLEN: Yes; there was no opening into the stomach.

CLINICAL DIAGNOSIS

Obstructive jaundice.

DR. LINTON'S DIAGNOSIS

Carcinoma of the pancreas?
Chronic pancreatitis?

ANATOMICAL DIAGNOSES

Chronic pancreatitis, severe, with stenosis of common bile duct.

Obstructive biliary cirrhosis of liver.

Cholelithiasis.

Choledocholithiasis.

Ascites.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The biopsy showed that the pancreas was, as had been described at the second operation, very small and fibrotic. The sections from the autopsy material confirmed the biopsy sections, showing a diffuse interacinar and perhaps interlobular type of chronic fibrous pancreatitis. There was atrophy of the acinar cells and replacement of much of the parenchyma by fibrosis and lymphocytic infiltration so that only the islet cells and ducts remained. This was much severer in the region of the head of the pancreas but was also present throughout the organ. The opening of the bile duct at the ampulla was tiny, and the common bile duct above was markedly dilated, about 3 cm. in circumference. This stenosis had undoubtedly been produced by the surrounding fibrous pancreatitis. There was no carcinoma. In the common duct, as well as in the gall bladder, we found muddy material and a few small stones (0.5 to 1 mm. in diameter), which was evidence that the infection was still going on in the biliary tract.

The liver showed widespread fibrosis of the biliary type, with proliferation of the bile ducts characteristic of fairly long-standing obstructive jaundice. There were 2 liters of bile-stained fluid in the abdominal cavity. The anastomoses were intact, and I believe that death was due to liver failure. I find it hard to conceive that the bile duct was ever patent enough to allow for a closure of the anastomosis because of disuse. I think he was getting all his bile through the anastomosis until it closed. Why, I do not know.

DR. ALLEN: My reasoning about it is that at the time of the first operation the pancreas was tremendously swollen, four times the normal size, from the inflammatory process, that the edema around the pancreatic portion of the duct produced the jaundice and then when the anastomosis was established the inflammation in the pancreas receded enough afterward to allow a temporary passageway for the bile to go through its natural course. During the temporary normal passageway, the anastomosis shut down. The duct did not completely close off—again due to the fibrosis—until one of these 1-mm. stones got down into

the narrow channel. That probably explains the question Dr Linton asked about the suddenness of the final jaundice. As a matter of fact it took two or three weeks for it to become complete.

DR CASTLEMAN: I do not believe that the bile duct would open when the pancreas became scarred, in fact this might tend to close it more completely.

DR ALLEN: We have had many cases of jaundice associated with pancreatitis that have completely cleared up. I have seen only one previous case of complete fibrosis of the pancreatic portion of the bile duct. It may happen quite frequently, but that is the only other one I have seen. In that patient the pancreatitis was secondary to a penetrating duodenal ulcer.

DR CASTLEMAN: This is the first true case of widespread chronic pancreatitis that I have ever seen. Mild degrees of focal chronic pancreatitis are not uncommon autopsy findings, but this severe form is distinctly unusual.

DR LINTON: The original obstruction could have been due to edema. Fibrosis would take months.

DR ALLEN: Yes, 'edema' is the word for the early episode, and fibrosis for the final one.

DR JONES: Furthermore, the patient had a slight amount of bile going through until the day of operation. X-ray films taken three weeks before failed to show barium going into the gall bladder, which it will do if the stomach is patent.

DR ALLEN: That is correct. At the second admission roentgenograms showed no passage of barium from the stomach to the gall bladder.

DR JONES: Dr Allen and I discussed this case after operation. If we were confronted with a situation like this, where the liver was badly damaged, it would be worth considering a two-stage operation, simply relieving the block for the moment with drainage and doing the complete operation later. This is all in retrospect, but I think it should be mentioned.

DR ALLEN: I have disliked doing two-stage operations for this type of obstructive jaundice because we rarely succeed in getting to the second stage. Sudden decompression of the liver has caused the patient to continue his decline. Possibly we should have been smart enough to have thought of operation when the dye retention rose to 60 per cent. We may never see another patient like this. It is an unusual case.

DR LINTON: I wonder why you did not do the Roux type of operation rather than cholecystectomy at the first operation.

DR ALLEN: I expected this to be a temporary affair and planned to disconnect it after the patient had recovered from the pancreatitis. I did not suppose he would develop fibrosis.

CASE 29312

PRESENTATION OF CASE

First admission. A seventy-nine year old Italian laborer entered the hospital because of a chronic ulcer of the right elbow occurring in the scar of an old burn.

Approximately forty years prior to admission the patient burned both elbows severely. These healed slowly with a great deal of scarring but without limitation of joint motion. Approximately one year prior to admission the scar about the right elbow ulcerated, often bled a great deal and never completely healed despite local treatment.

The family and past histories were noncontributory.

Physical examination disclosed a fairly well preserved old man who seemed apprehensive. The heart, lungs and abdomen were normal. On the dorsal aspect of the left elbow over an area approximately 5 by 4 cm., involving the lower end of the upper arm and an equal area of the lower arm, were irregular scars traversed with many firm crusted ridges. The involved area of the right elbow measured approximately 14 by 12 cm. and was almost symmetrical in position to that of the left arm. In the center was a shallow ulcer, 12 by 8 cm., covered by shreds of necrotic tissue, fresh blood and greenish-yellow purulent exudate. There was almost no granulation tissue.

The blood pressure was 148 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red cell count of 4,440,000, with a hemoglobin of 84 per cent, and a white cell count of 8200. The urine was normal. A blood Hinton test was negative.

X-ray films of the right elbow showed a large area of bone destruction from the upper one third of the shaft of the ulna with some soft tissue swelling. There was no evidence of new bone formation. There was a pathologic fracture through the area of destruction. A chest roentgenogram showed clear lung fields. There were several old fractured ribs on the right side. Following a report of epidermoid carcinoma, Grade 2, on a biopsy specimen from the edge of the ulcer of the right elbow, the right arm was amputated at the junction of the middle and lower thirds of the humerus. Dissection of the amputated limb showed extension of the neoplastic tissue from the base of the tumor into the subjacent proximal end of the ulna, with pathologic fracture 4 cm. from the proximal articular surface. Because of the severe local infections the patient received a preoperative course of sulfadiazine. He was discharged on the eighteenth hospital day.

Final admission (one year later). The patient re-entered because of fever, foul breath and pain in the right chest.

Following discharge the patient was well until four months prior to admission, when he developed a "cold," characterized by cough, fever, chills, sweating and a sharp pain in the left lower chest anteriorly. After three and a half weeks in his community hospital he apparently made a satisfactory recovery, and an x-ray film of the chest prior to discharge was said to have been negative except for "congestion." Three months before entry he had a tooth extracted under local anesthesia.

Approximately six weeks before entry he again developed a cough and complained of a sharp pain across the epigastrium and in the precordial area on coughing. He soon became extremely weak, lost his appetite and went to bed. Three days prior to admission he suddenly coughed up a large amount of bloody, foul-smelling material, and since then he had continued to bring up fairly large quantities of foul-smelling sputum, without blood. During the three days prior to admission he had several chills, with fever as high as 101°F.

Physical examination disclosed an emaciated man with a great deal of respiratory distress. The chest was large, and there was dullness to flatness with diminished breath sounds and coarse moist rales over the posterior right chest below the scapula. In the right axilla a loud "leathery creaking" sound was audible on both inspiration and expiration. There was no diaphragmatic excursion on this side. A blowing systolic murmur was audible over the entire precordium, best heard at the apex. Abdominal examination was negative. The right upper arm stump was well healed, and the scar about the left elbow had not changed since the previous examinations. There was no clubbing of the fingers.

The blood pressure was 115 systolic, 55 diastolic. The temperature was 100°F., and the pulse and respirations were normal.

A chest roentgenogram demonstrated a large abscess above the right diaphragm posteriorly, which was 7.5 cm. across at the fluid level. The abscess wall was rather thick and irregular, and the outlines not sharply defined. No definite tumor mass was seen in the hilar area.

Examination of the blood revealed a red-cell count of 3,800,000, with a hemoglobin of 13 gm., and a white-cell count of 16,000, with 82 per cent neutrophils. The urine was acid and had a specific gravity of 1.020; the sediment contained innumerable red cells, 4 to 6 white cells and several granular casts per high-power field. The sputum

was tenacious, foul smelling, and yellow green, with rusty streaks. Bronchoscopy showed no widening, deviation or fixation of the carina. The right upper and middle lobe orifices were normal. The mucosa throughout the right main and lower lobe bronchi was markedly reddened and somewhat edematous and contained a considerable amount of a brownish-red, thin secretion. This appeared to be coming from the lower lobe bronchus, but its exact origin could not be determined. The mucosa was smooth, and there was no intrinsic mass or evidence of extrinsic pressure.

The patient continued to run a fever ranging between 100 and 102°F. Postural drainage was ineffectual, and on the thirteenth day a first-stage drainage of lung abscess was performed. A chest roentgenogram the next day showed no change in the abscess cavity. In addition there was an area of consolidation in the left mid-lung field. Four days later the second stage was done. The patient died soon after operation.

DIFFERENTIAL DIAGNOSIS

DR. RALPH ADAMS*: The assumption that chronic irritation was an etiologic factor in the production of this cancer from a burn scar seems to be admissible without argument. The carcinogenic role of continuing low-grade injuries to tissues by infection and by mechanical, thermal and chemical irritants has been well established and is generally accepted. Taylor, Nathanson and Shaw¹ reviewed 430 cases of carcinoma of the extremities and found definite precancerous lesions to exist in 196 cases. Eleven cancers occurred in the sinuses of chronic osteomyelitis, 13 in varicose ulcers, and 23 in the scars of old burns. The 11 cases of cancer found in osteomyelitis sinuses all had appeared in lesions more than fifteen years old. I know of no case in which cancer has appeared in a chronic varicose ulcer in a shorter period. There is in the literature no report of carcinoma appearing primarily in an empyema sinus, but I have one unpublished case in which epidermoid carcinoma developed in a chronic empyema sinus twenty-six years after its onset. However, highly malignant cancer has been observed in scars of old burns within two years. The point being made is that an ulcer appearing in an old burn scar more than fifteen years after the original injury is almost surely malignant and should be treated as such immediately.

This hospital had no opportunity to offer treatment until the cancer had advanced to bone destruction and carried out the appropriate therapy—amputation. Metastatic disease in the chest, the commonest site of carcinomatous metastases

*Surgeon, Lahey Clinic.

from the upper extremity, was properly excluded so far as possible by negative chest roentgenograms preoperatively.

Within eight months, however, the patient developed signs of lung and pleural involvement and received clinical relief of symptoms by rest in his local hospital; however, x-ray signs of "congestion" persisted, indicating that he had more serious disease than a "cold" or congestion or simple bronchopneumonia. A week after leaving the local hospital and three months before coming here he had a tooth extraction under local anesthesia. Six weeks thereafter and six weeks before entry here, he again developed signs of pneumonitis with infection, and three days before entry a diagnosis of putrid lung abscess was made, which was self-evident when he coughed up foul, bloody pus.

The record is not clear on this detail but I dare say that the patient was never entirely free from cough and a sensation of something wrong in his chest from the original chest episode four months prior to entry until his eventual admission, for the following reasons. In the first place, six weeks is an unusually long interim between a tooth extraction and the appearance of a lung abscess if such is developing. An additional five weeks, for a total of eleven, is in my experience unique between the onset of suppurative pneumonitis and the production of foul sputum. Secondly, according to statistics, a patient with this diagnostic and symptomatic background should have malignant disease in his chest. Thirdly, although the record does not mention it, the first chest x-ray film at the time of the second admission shows distinct erosion of the left fifth rib and adjacent translucence in the peripheral lung field, as well as the described abscess in the opposite lung. Fourthly, the walls of the abscess are much denser and thicker and more irregular than one is accustomed to see in putrid lung abscess but are characteristic of abscess secondary to malignant degeneration. And, finally,—and I shall ask the X-ray Department for confirmation or rebuttal in a moment,—it is my impression that the chest x-ray film taken one day after the first-stage drainage of the right lung abscess, and twelve days after the previous film, reveals marked destruction of the left fifth rib and pathologic fracture in addition to the area of consolidation in the left mid-lung field cited by the case abstract as having just appeared. A few years ago the statement was frequently made that metastatic pulmonary lesions do not cause hemoptysis, but since then a few exceptions have been encountered,² and we have to abandon the rule as a statement of invariable fact; it is, however, a good

generalization. Similarly, I have one proved example that metastatic malignancy can suppurate to produce bloody and foul sputum, and I believe that this case furnishes a second example. The bronchoscopic findings are consistent with that theory. The point whether the abscess is pyogenic or cancerous is an academic one, but it is a feature of the case that requires discussion.

Before making a final diagnosis may I have a first-hand interpretation of the films from the X-ray Department?

DR. BENJAMIN CASTLEMAN: The following statement appears in the x-ray report, "The posterior portion of the left fifth rib cannot be traced as it crosses the area of involvement. I believe the patient should have a film of the rib." Apparently that film was never taken.

DR. MILFORD SCHULZ: It is quite obvious that the posterior portion of the left fifth rib is involved. Certainly the short interval of time suggests that the rib must have been involved in the earlier film. Yes, it is; here is an area of destruction in the same place—apparently a fracture occurred in the meantime.

DR. ADAMS: In my halting clinical way I hesitated to arrive at a diagnosis of the rib lesion and took the liberty to ask Dr. Hugh Hare, a radiologist, to check that finding, which he did.

In conclusion, I shall state my diagnosis as carcinoma in an old burn scar of the right arm, with chest-wall and pulmonary metastases and putrid lung abscess.

DR. HELEN PITTMAN: When I saw this man,—I acknowledge that I missed the lesion in the rib,—he obviously had a stinking lung abscess. I cast my vote in favor of its being distal to an intra-bronchial metastasis, going on the same reasoning as Dr. Adams has used.

CLINICAL DIAGNOSES

Lung abscess, right lower lobe.
Carcinoma of lung (? primary or metastatic),
right lower lobe (?).
(Carcinoma of right arm.)
Amputation of right arm.

DR. ADAMS'S DIAGNOSES

(Epidermoid carcinoma, in scar of burn of right arm.)
Metastatic epidermoid carcinoma of lungs,
with secondary suppuration, and of ribs.

ANATOMICAL DIAGNOSES

(Epidermoid carcinoma in scar of burn of right arm.)
Metastatic epidermoid carcinoma of lung, right
lower lobe, with secondary suppuration.

Metastatic epidermoid carcinoma of ribs and liver.
Pulmonary abscesses, left upper lobe.
Empyema, bilateral.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The second-stage drainage of the large abscess was done, and at that time a biopsy of the wall of the abscess was made. The diagnosis was epidermoid carcinoma. The patient died the day following the drainage.

At autopsy there was empyema on both sides. The abscess had been unroofed and was lined with shaggy gray-green granular tissue. Although grossly it looked like an ordinary lung abscess, epidermoid carcinoma was found in its wall microscopically. In other words, all but a rim of tumor had become necrotic. This was not an abscess distal to a tumor but one within the tumor. In the left upper lobe there were two abscesses that in gross looked very much like the one in the right lower lobe, but sections of both these abscesses showed no evidence of carcinoma. They appear to have been secondary lung abscesses, probably from the infected tumor. Unfortunately no section of the rib was made, but there is no

doubt that it would have proved to be metastatic epidermoid carcinoma. A section of the liver also showed metastatic tumor.

When I first saw the biopsy specimen of the right lower lobe I was doubtful whether it was a primary carcinoma of the lung or a metastasis from the carcinoma of the arm. The former is still a possibility, but the peripheral location of the lesion and the similarity of the histologic appearance of the two cancers make metastatic carcinoma more likely. The bone and liver metastases could come from either primary tumor.

DR. FLETCHER H. COLBY: Did you find the source of the blood in the urine?

DR. CASTLEMAN: No. There were a few changes in the tubules that suggested degeneration, perhaps due to drug therapy, but I hesitate to say much about it because the autopsy was done sixteen hours after death, when one usually finds post-mortem tubular degeneration.

PROCUREMENT AND ASSIGNMENT OF NURSES

LAST week the War Manpower Commission announced that its subdivision in charge of nurse procurement and assignment, the Nursing Supply and Distribution Unit, had been made an integral part of the Procurement and Assignment Service. The Nursing Division will be supervised by the Directing Board, of which Dr. Frank H. Lahey is chairman, and as with the divisions covering physicians, dentists, sanitary engineers and veterinarians, the latter is charged not only with recruitment of sufficient nurses to meet the needs of the armed

forces but also with minimum adequate nursing care for nonmilitary governmental agencies, the civilian population and industry.

Two nurses, Miss Katherine Tucker, of Philadelphia, and Miss Laura Grant, of New Haven, Connecticut, have been appointed to the Directing Board, and the latter will be assisted by the Nursing Advisory Committee, in addition to newly appointed representatives on the already existing advisory committees that are concerned with problems affecting nurses. The work at the Washington office will be under the direction of Miss L. Louise Baker, an assistant executive officer of the Procurement and Assignment Service, assisted by Miss Ruth A. Heintzelman.

The field activities of the Nursing Division will be carried out by state and local committees. At the former level, the Supply and Distribution Committee of the Nursing Council for War Service, which represents the various nursing organizations in each state, will act as the State Committee for Nurses of the Procurement and Assignment Service; whereas local matters will be handled by the nursing councils in each community. Both the state and the local committees will function independently of but in co-operation with the corresponding committees having to do with the procurement and assignment of physicians.

Because of all this it seems likely that many of the present-day problems dealing with nurses will be handled more expeditiously and more efficiently than they have been in the past.

ARNOLD CARL KLEBS*

THE death of Arnold Carl Klebs, a distinguished American physician, in Nyon, Switzerland, on March 6, 1943, brings to a close a life of unusual achievement in medicine and medical bibliography. Known to comparatively few physicians of the present generation in America, his influence, nevertheless, was widespread among a small group of doctors particularly interested in medical history.

*An exhibit of books, pamphlets and pictures having to do with Dr. Klebs is now on display in the rotunda of the Boston Medical Library.

As a specialist, moreover, he was a leading figure in this country at the turn of the century in the fight against the "great white plague." In later years his work as the bibliographer of the scientific and medical incunabula was deeply appreciated in scholarly circles. Klebs, like his predecessor, Conrad Gesner, kept his home open in Switzerland to a host of American visitors who found his delightful villa at Nyon, on the shore of Lake Geneva, a welcome resting place in their peregrinations about Europe. Many a weary doctor, exhausted from a great international congress, sought relaxation in this quiet retreat. One found, moreover, an energetic and active man ready to exchange ideas in a stimulating and brilliant manner, often prodding his friends to bring out the best that was in them, and at the same time adding to the conversation, based on a wealth of experience, a keen summary from his own mind. Klebs was, moreover, an ardent correspondent with physicians both in Europe and America. In modern times he must have had few equals, and his pungent, philosophic letters are now the treasured possessions of many who kept this literary and scientific bond throughout the passing years.

Son of Edwin Klebs,¹ an early student of pathology and the co-discoverer with Loeffler of the diphtheria bacillus, Klebs was born in Berne, Switzerland, on March 17, 1870. His early years were peripatetic for, before he received his medical degree at Basel in 1895, his father had held successive chairs in the universities at Berne, Würzburg, Prague, Zurich and Carlsruhe. Klebs became well grounded in the classics and spoke and read with equal facility German, French, Italian and English. One can hardly conceive of a training wider in scope, and as the years went by, he always stood out as an internationalist of the first degree. Because of his facility in languages, he could easily and quickly grasp facts and ideas difficult for many because of language deficiencies. His keen mind, moreover, seemed to miss little.

After receiving his medical degree² in 1895, Klebs served as an instructor in pathology in Zurich, spent a summer as locum tenens at Vitznau and carried on some postgraduate studies at London and Paris. It was this thoroughly trained and brilliant student who came to America with his father in 1895. The elder Klebs first settled in Asheville, North Carolina, where he conducted laboratory and clinical investigation in a private tuberculosis sanatorium. Within a year, however, he was called to the chair of pathology at Rush Medical College in Chicago, a position that he held until 1900, when he returned to Europe. Before he left, his son, who in 1898 married Margaret Forbes, daughter of J. Malcolm Forbes, of Milton, Massachusetts, went to Chicago to practice, after having acted as head of a tuberculosis sanatorium in Citronelle, Alabama. He became a citizen of the United States in 1904 and remained in Chicago until 1909. During this period his main interests were in tuberculosis, and he soon became a recognized leader in the field. As director of the Chicago Tuberculosis Institute he was an ardent advocate of the open-air treatment, then an innovation, and he energetically supported the early work of Trudeau and others. Klebs's forceful personality was soon recognized by Billings, Musser, Jacobs, Osler and other students of tuberculosis throughout America. He worked hard, reading papers in various parts of the country, and finally culminated his endeavors in the editorship of a volume by American authors entitled *Tuberculosis*,³ published in 1909. As a background for this book he collected over three thousands reprints of articles on tuberculosis. These he carefully analyzed and published as a bibliography appended to the work. For authors he sought the best in the field, and contributions were forthcoming from Baldwin, Brown and Trudeau, of Saranac, Biggs, of New York, Coleman, of Augusta, Georgia, Minor, of Asheville, North Carolina, and Webb, of Colorado Springs. Unusually clear Roentgen plates for the time were furnished by Cole, of New York.

This volume was the best summary in English of the subject in 1909 and still may be read with profit. Klebs kept his interest in tuberculosis after 1909, although he did not take an active part in the campaign against it except on rare occasions. At the Fifteenth International Congress on Hygiene and Demography, held at Washington in September, 1912, he served as vice-president of the Section on the Control of Infectious Diseases.

Before his retirement in 1909, Klebs had married for a second time, his first wife having died in 1899. He went to Switzerland to live, first at Ouchy-Lausanne, and later at Nyon. Although making his home abroad, Klebs made frequent visits to the United States, and indeed lived in Washington during the period of World War I and in New York City subsequently for extended periods. Although he never forgot his adopted country, his heart was in his native Switzerland, and there at Nyon he established his library, using a small building on the grounds of his villa for this purpose. This two-story structure was literally lined with books and it became a true workshop of an intense, ardent spirit who exhibited, as few others have done, Osler's master word in medicine, "work." In this building, so delightfully situated, he deposited his father's books on pathology and allied subjects and assembled the apparatus necessary for his historical research.† Whatever he did, he did thoroughly, and each paper that came from his pen in later years was the result of many hours and even years of carefully planned research.

Klebs first historical investigation concerned variolation, stemming from his father's interest in the subject. To his review of the subject,⁴ read before the Johns Hopkins Hospital Historical Club in 1912, he characteristically added a bibliography of six hundred items, and followed this with a paper in German on the same topic in 1914. This work brought him in contact with early American medicine: Zabdiel Boylston, Cotton Mather, New England and the Indians, subjects

which continued to interest him throughout his life.

His next major work related to Leonardo da Vinci. He read a paper on da Vinci's anatomical studies⁵ before the Society of Medical History of Chicago in 1915, at the same time, no doubt, renewing his old friendships in that city. He was living in Washington at the time, working in the Army Medical Library, and had already started his studies on incunabula, using the collection in that library as the basis for his fundamental researches in this field. He began by cataloguing those at hand, and soon contributed some sound ideas regarding classification of incunabula in general.⁶ Klebs's scheme was widely adopted by librarians and cleared up many points in descriptive labeling. He was soon led to the fifteenth-century herbals, books scarcely recognized at the time as a distinctive group, and he compiled an extensive catalogue. He⁷ later wrote that he had "travelled thousands of miles to visit libraries, to consult numerous catalogues, had an endless correspondence, hundreds of photographs, only to complete and later to correct the data of my list." A similar list of plague tracts⁸ was made, followed by more extensive investigations with Sudhoff,⁹ published in 1926. These authoritative listings have now become the standard references to the subjects and testify to Klebs's sound scholarship in both their completeness and accuracy.

Various papers on incunabula, appearing from 1926 to 1938, culminated in his classic short-title list of scientific and medical fifteenth-century books,¹⁰ a book constantly referred to by medical bibliographers throughout the world. It was to have been an introduction to a more extensive study, for Klebs had collected photographs and complete descriptions of over three thousand incunabula of medical or scientific interest, and this material lay in his library, ready to be brought to light, at the time of his death. Superbly ordered, it only awaits the final touches of some future scholar. The short-title list, however, is a royal monument to a man whose life was de-

†Dr. Klebs's library will eventually be transferred to the Historical Library of Yale University School of Medicine, where it will be added to the Cushing-Fulston Collection.

voted to sound bibliographic research, and because of it, all scholars are grateful.

Some estimate of the affection and esteem with which Klebs was regarded can be gained from the number of papers published in his honor on his seventieth birthday in 1940. Because of the war most of his European friends were unable to contribute to a birthday volume; however, the Institute for the History of Medicine at Johns Hopkins University issued a large, special number of its bulletin containing papers by his friends and associates.¹¹ Never a teacher or head of an institute, he had no pupils in the usual sense of the word; but his influence was widespread, and he inspired a group of contemporaries to expand the cultural side of medicine by his writings and by the impact of his forceful personality. In America, his adopted country, he left an enduring stamp on humanistic studies and on the history of medicine.

MEDICAL EPONYM

ADIE SYNDROME

This was discussed by William John Adie (1886-1935) in an article entitled "Pseudo-Argyll Robertson Pupils with Absent Tendon Reflexes, a Benign Disorder Simulating Tabes Dorsalis," which appeared in the *British Medical Journal* (1:928-930, 1931). He writes:

I wish to draw attention to a benign symptomless disorder characterized by pupils which react on accommodation but not to light, and by absent tendon reflexes.

Five of the six cases I am about to describe came under my notice in the course of a few weeks; the condition therefore cannot be very rare. Though harmless in itself it merits recognition because it is often mistaken for a manifestation of syphilis of the nervous system, with unfortunate consequences for the patients and their families. . . .

. . . . The true Argyll Robertson pupil reacts promptly and fully, often excessively, on convergence, and dilates again as soon as the effort to converge the visual axes is relaxed. In these cases the pupils show the so-called myotonic reactions; they do not respond to light; they contract very slowly through a wide range during a sustained effort to converge; often remain small long after the effort ends, and, when they dilate again, do so slowly.

It seems to me more than probable that some . . . cases with non-luetic Argyll Robertson pupils but normal tendon reflexes are examples of a milder form of the same benign disorder that I have described here.

R. W. B.

OBITUARIES

CLARENCE JOHN BELL

1876-1943

He was the greatest Roman of them all.

It is difficult adequately to evaluate such a versatile personality as Dr. Bell. He typified the highest traditions of the country doctor. His casual mode of dress concealed an alert, well-disciplined mind and character. He had a direct incisive approach to everything he undertook. His medical skill and judgment was of such a character that he held a dominant position throughout his section of the Cape. Not only was he prominent professionally, but as a practical economist his opinion was widely sought. Dr. Bell was a director of the local bank, treasurer of the Methodist Church, a member for many years of the school board and an active supporter of "every good work."

Kindliness, tact and a love of his fellow man were conspicuous qualities that he possessed in full measure. The by-products of his practice, such as the payment of overdue mortgages without thought of personal recompense, and the successful solution of domestic difficulties among his patients, are legion. He possessed a delightful sense of humor, which colored all his dealings.

Wellfleet, to its everlasting credit, appreciating the man and his services, gave a public testimonial dinner in his honor two years ago. All who knew him genuinely mourn the passing of this noble soul.

Besides his wife, he leaves a daughter, Mrs. Stephen Daniel and a son, Richmond.

L. F. J.

MAURICE GERSTEIN

1870-1943

Maurice Gerstein, a practicing physician for forty five years, died suddenly on July 12, 1943, at Beth Israel Hospital, Boston. Born in Russia on March 1, 1870, he came to this country in 1888 and graduated from New York University Medical College in 1896.

He was a typical successful family doctor who gained the love and esteem of his patients. His records show that during his long practice he was the attending obstetrician in over five thousand deliveries. He was also successful as an organizer, having been a charter member and the first secretary of the medical staff of the former Mount Sinai Hospital, Boston, and a founder of the Greater Boston Bickur Cholim Hospital and the New Century Club. He was an ex-president and supervising censor of the Norfolk District Medical Society and a member of the American Medical Association, the Greater Boston Medical Society and many charitable organizations.

During World War I, he volunteered in the Medical Service Corps, a local medical group, and was appointed chairman of the Soldier's Relief Commission in Ward 16.

Dr Gerstein was the author of several articles published in various medical journals. He was a founder of the former periodical *The Mount Sinai Monthly* and editor of *The Medical Directory of Greater Boston*, published in 1906.

His sudden death was a shock to his many associates, friends and relatives. He left a landmark in Boston medical and communal life, and died after a full, active and useful life.

S R K

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CONNOR—THOMAS J. CONNOR, M.D., of Arlington, died July 16. He was in his fifty-second year.

Dr Connor received his degree from the Boston University School of Medicine. He was a member of the Massachusetts Medical Society and the American Medical Association.

CURRAN—LOUIS F. CURRAN, M.D., of Dorchester, died July 22. He was in his fifty-eighth year.

Dr Curran received his degree from Tufts College Medical School in 1917. At the time of his death he was physician-in-chief of the medical department of the Carney Hospital and clinical professor of medicine at Tufts College Medical School. He was a member of the Massachusetts Medical Society, American Medical Association, American Gastroenterological Association, John Bottomley Medical Society, St. Luke's Medical Guild and the Louis Pasteur Medical Society.

He is survived by his widow, three sons and a sister.

JACKSON—ALTON A. JACKSON, M.D., of Everett, died July 25. He was in his ninetyeth year.

Dr Jackson received his degree from Harvard Medical School in 1883. He was founder of the Whidden Memorial Hospital and the Everett Visiting Nurses Association. He was a member of the Massachusetts Medical Society and the American Medical Association.

Two sons and a daughter survive.

CORRESPONDENCE

RELOCATION OF PHYSICIANS

To the Editor: The following letter from a physician who has gone into a rural area that was lacking in medical services expresses so clearly and understandingly what has been and is being done throughout the country that I believe it deserves publication.

FRANK H. LAHEY, Chairman
Directing Board

Procurement and Assignment Service
War Manpower Commission
Washington, D. C.

• • •

Dear Dr. Lahey:

It has occurred to me that the following might interest you in connection with your procurement program.

I am sixty-seven years of age, and after specializing in urology for thirty years, came here in November at the request of the Board of Selectmen to take over the practice of the late Dr. Damon.

Wilbraham has a population of 3000 and covers 22 square miles. With the exception of a small Polish group, most of the people are middle-class Americans. The town has no hospital, no drugstore and no district nurse.

Because I was a member of the Massachusetts Medical Society and also came recommended by several well known medical men in Boston, I was accepted at once by the people, and in two weeks had all I could do.

There are several conclusions that I have arrived at in connection with a medical man past the Government age coming from the city into a country practice. First, it is not necessary or essential for him to make connections with a hospital in a nearby city. The people here wish to be sent to a specialist in Springfield in cases of serious illness, and the medical man has no time even to make a visit on his patient after turning him over to a Springfield consultant. Secondly, I believe that it is impracticable for an older medical man to assume the responsibility of practice in one of these towns unless he has kept up with modern medicine. It is amazing to learn the amount of knowledge the local people have of the newer drugs and newer methods of treatment. An important contributing factor in this is that the public schools have a number of medical examinations throughout the year at which the parents are present. And, finally, it is my opinion that the older medical man need not hesitate to practice in the country owing to fear of night work. The people are most considerate and believe that their doctor must be saved as much as possible from over work. Night calls, except in a rare emergency, can be handled over the telephone, and a call made the following morning. However he must be prepared to see a certain number of people in his office in the evening, since most

of the people are working during the day, and transportation presents difficulties.

The incoming doctor must make up his mind that at least 75 per cent of the work during the winter—November to April—consists of house calls. There are many reasons for this: severe illnesses, fear of contagious diseases on the part of patients, and the ever-increasing transportation problem. The doctor must take his time in his examinations, both in the home and in the office. The visit of the medical man is an event in many of their lives, and it must not be hurried. This is extremely important.

In conclusion, I believe that you, as head of the Procurement and Assignment Service, might help the overworked country medical man by publicizing the idea that the people should notify their medical man in the morning if they expect to see him the same day. I feel very strongly about this and hope that much publicity may be given to it. We country doctors work seven days a week; our meals are always interrupted, and we have little time with our families.

EDMUND L. SAUNDERS

Willbraham, Massachusetts

NEW PREMARITAL BLOOD-TEST LAW

To the Editor: The following letter was recently forwarded to all physicians licensed to practice in Massachusetts.

VLADO A. GETTING
Commissioner of Public Health

State House
Boston

* * *

Dear Doctor:

A new premarital blood-test law has recently been passed and goes into effect immediately.

The new law (Section 28A of Chapter 207 of the General Laws) is essentially the same as the old, except for the following points, which we call to your attention:

(1) Under the new law the examination "shall be made only to ascertain the presence or absence of evidence of syphilis, and shall include a serological test for syphilis."

(2) The law now provides that the health certificate need not be presented until the time of issuance of the marriage license, and the examination and laboratory test must be made not more than thirty days before the date the *marriage license is issued*.

(3) The law now provides that the examination may also be made by "a physician registered or licensed to practice in any other state of the United States."

Until a new supply of forms is available, the old form will be accepted. We suggest that the section number in the next to the last line of the certificate be corrected to read "in accordance with section *twenty-eight A* of chapter two hundred and seven of the General Laws."

VLADO A. GETTING, M.D., Dr.P.H.
Commissioner of Public Health

BOOK REVIEWS

First Aid: Surgical and medical. By Warren H. Cole, M.D., and Charles B. Puestow, M.D., Ph.D. 8°, cloth, 351 pp., with 92 illustrations. New York: D. Appleton-Century Company, Incorporated, 1942. \$3.00.

This volume on surgical and medical first aid is one of the most complete that has ever been called to the reviewer's attention. The large number of contributing authors, each an expert in his subject, adds much to the value of the work. All the twenty-one chapters are worthy of most careful reading. Every conceivable question seems to be well covered, and the graphic illustrations are excellent. All the most important advances in the treatment of injuries, such as burns, with accompanying shock, and the correct methods for first aid in the treatment of fractures, are given most careful consideration, with helpful illustrations of transference of the injured with a minimum amount of disturbance and pain.

The first part of Chapter I, entitled "Precautions and Limitations in First-Aid Work," deserves particular attention. Here the question of errors in judgment is taken up. An instance of this is shown in the statement in which the authors truthfully say, "The indiscriminate use of the tourniquet of which first-aid workers are so frequently guilty is often an error in judgment." In the conclusion of this chapter the authors state: "We wish forcefully to remind the first-aid worker of the old proverb which warns us so truthfully that 'a little knowledge is a dangerous thing.' The first-aid worker must know his own limitations in knowledge and ability and abide by them."

This book well deserves a thorough and careful reading by all those who are interested in surgical and medical first aid.

Mental Health in College. By Clements C. Fry, M.D. With the collaboration of Edna G. Rostow. 8°, cloth, 365 pp. New York: The Commonwealth Fund, 1942. \$2.00.

The material covered in this book has been gathered in the last ten years by the Department of Psychiatry and Mental Hygiene at Yale University. A mental-hygiene service for students was first inaugurated in 1925 by Dr. Arthur Ruggles, but in the last ten years the work has been carried on by the author of this monograph. The book is a thorough study of mental disease as it appears in college students and is the best study of its type known to the reviewer.

The book is extremely well written, and the problems clearly set forth. There are illustrative case histories. The material was gathered not only from the undergraduate department but also from the postgraduate divisions of the university, where, incidentally, one is surprised to learn that there are so many mental maladjustments. The Commonwealth Fund has made this publication available at a reasonable price, and it is hoped that the book will be widely distributed. It can be recommended without reservation, and should be of use to all educators and to the medical profession in general.

PROTHROMBIN DEFICIENCY IN BILIARY OBSTRUCTION AND DISEASES OF THE LIVER*

FREDA K. HERBERT, M.B., B.S.

NEWCASTLE-UPON-TYNE, ENGLAND

DURING the last seven years the explanation of the tendency to hemorrhage in diseases of the liver and biliary tract has been established, and satisfactory prophylactic measures are now available for patients with obstructive jaundice or biliary fistula. The maintenance of normal plasma prothrombin depends on an adequate supply and absorption of vitamin K. The actual relation between vitamin K and prothrombin formation is not clear, but it is known that prothrombin is formed in the liver, and that hypoprothrombinemia may result from lack of vitamin K, deficient absorption of the vitamin or gross damage to the liver parenchyma. In obstructive jaundice or biliary fistula the primary defect is in absorption, since vitamin K, like the fats and other fat-soluble substances, is not absorbed when bile salts are absent from the intestine. Therefore a large proportion of such cases show a low level of plasma prothrombin, and when this deficiency is serious there is a risk of hemorrhage following operation. The deficiency can be corrected by oral administration of bile salts, but this is a relatively slow process. The deficiency can be rapidly corrected by injection of vitamin K or its analogues, which are naphthoquinone derivatives. There are two naturally occurring vitamins. Vitamin K₁ derived from alfalfa, is 2-methyl-3-phytyl-1,4-naphthoquinone; vitamin K₂, derived from putrefied fish meal, is 2,3-difarnesyl-1,4-naphthoquinone. The phytyl and farnesyl side chains in these substances are not connected with their biologic activity, and several simpler naphthoquinones are as effective as the natural vitamins, or even more so. Apparently the most active analogue is 2-methyl-1,4-naphthoquinone, which is available for therapeutic use.

It has been established that estimations of plasma prothrombin often give warning of the risk of postoperative hemorrhage in cases in which there

is no spontaneous hemorrhage, and no abnormality in coagulation time or bleeding time. The estimation of prothrombin is therefore a useful clinical test, as showing when prophylactic treatment is necessary. However, there is usually a fall in plasma prothrombin following operations on the biliary tract, so that a normal value before operation does not necessarily exclude risk. Probably the main factor in this postoperative fall is manipulation of the liver (Lord¹ and Cullen, Ziffren, Gibson and Smith²).

In diseases of the liver associated with gross damage to the hepatic parenchyma, hypoprothrombinemia is of common occurrence, and is due not only to the defective absorption resulting from absence of bile from the intestine, but also to failure of the liver to manufacture prothrombin even when vitamin K is available. In such cases the plasma prothrombin does not rise in response to treatment with the vitamin. It is therefore necessary to bear in mind the possibility of associated liver disease in patients requiring operations on the biliary tract.

The evidence by which these facts were established has been reviewed by Brinkhous³ and by Butt and Snell.⁴ Recently numerous other authors have confirmed and extended observations on all the important points. Macfie, Bacharach and Chance⁵ reported the successful use of 2-methyl-1,4-naphthoquinone, given intramuscularly, in correcting hypoprothrombinemia in obstructive jaundice, and numerous authors⁶⁻¹³ have reported experience with this and with other naphthoquinone derivatives, which confirms the effectiveness of the treatment in obstructive jaundice and its failure in many cases of disease involving the hepatic parenchyma.

Methods for the estimation of plasma prothrombin fall into two categories—one-stage and two-stage technic. The one-stage type was introduced by Quick (Quick, Stanley-Brown and Bancroft¹⁴ and Quick²⁰) and has been popular on account of

*From the Department of Pathology, the Medical School, King's College, and the Royal Victoria Infirmary Newcastle upon Tyne, England.

its simplicity. It depends on the time taken to form a clot when suitable amounts of calcium and thromboplastin are added to plasma. During the short time required for coagulation, only a very small proportion of the plasma prothrombin is converted into thrombin; the clotting time depends on the rate of thrombin formation. The rate of formation of thrombin depends on the prothrombin titer, and the clotting times obtained with any given plasma can be expressed in terms of prothrombin titers by comparison with a calibration curve based on serial dilutions of normal plasma. There have been many modifications of the one-stage procedure, some designed to give a rapid and simple means of detecting serious prothrombin deficiency, and others aiming at greater accuracy. For the maximum accuracy it is essential to use serial dilutions not only of the normal standard plasma but also of the plasma to be tested. Careful standardization of thromboplastin is also necessary. All methods of the one-stage type are, however, open to the objection that they are based on the rate of formation of thrombin from prothrombin, and that this may be affected by other factors besides the prothrombin titer. These other factors are especially important when comparisons are made between different species, or between infants and adults.

This difficulty is avoided in the two-stage method introduced by Warner and his associates (Warner, Brinkhous and Smith²¹ and Smith, Warner and Brinkhous²²). In this method the plasma, in high dilution, is treated with calcium and thromboplastin and incubated until thrombin activity is maximal. The thrombin formed is then estimated from the time taken for formation of a clot with added fibrinogen. This is much more satisfactory in principle than the one-stage method. The factors involved in it have been studied by me^{23, 24} and a modification described.

The present paper describes experience with the two-stage method of estimating plasma prothrombin in obstructive jaundice and diseases of the liver. Its main contribution to the subject is additional evidence concerning the incidence of hypoprothrombinemia in these conditions, based on an accurate technic. There are also examples of the correction of the prothrombin deficiency by treatment in cases of obstructive jaundice, and the lack of response in liver diseases. Plasma phosphatase has been estimated in a large proportion of the cases by the method of Jenner and Kay,²⁵ and in some cases the diagnosis was assisted by the use of the levulose tolerance test, with analyses of blood levulose (Herbert²⁶).

RESULTS

Biliary Obstruction

In all, 79 cases of obstructive jaundice have been examined. In 18 of these the jaundice was only slight, with the serum bilirubin not more than 2.4 mg. per 100 cc., and among these there were only 3 cases of prothrombin deficiency. These showed prothrombin titers of 68, 73 and 74 per cent of the normal average (normal range, 80 to 120 per cent of normal average). There were also 10 cases that were first examined after treatment had begun. Although some of these will be referred to later, they are excluded from the main table.

The remaining 51 cases, with moderate or intense jaundice, are described in Table 1. The prothrombin titers are those found before treatment was given. They were normal in only 16 cases, the remainder being between 50 and 80 per cent of normal in 19 cases, and less than 50 per cent of normal in 16 cases.

There is no regular correlation in this group between serum bilirubin and prothrombin, or between phosphatase and prothrombin. Although, in general, severe and long-standing biliary obstruction tends to yield the highest phosphatase and lowest prothrombin titers, there is no constant association between high phosphatase and low prothrombin in single cases. Close correlation could hardly be expected, because even if the severity and duration of obstruction were the only factors affecting the rise in phosphatase (which is uncertain), the prothrombin would be affected also by other factors. There may have been coincidental liver damage in some cases, and variations in the vitamin K intake may have had some effect where obstruction was partial or intermittent and absorption not entirely suppressed.

There is a definite relation between the prothrombin titer and the duration of obstruction. This point is best shown by considering obstruction due to malignant disease, since in these cases it was persistent. Malignant disease was the cause of obstruction in Cases 9 to 41, inclusive, which are listed in Table 1 in order of the duration of jaundice. They may be conveniently considered in two groups—one of 19 cases in which jaundice had been present for not more than four weeks, and one of 14 cases with longer duration of jaundice. The range of prothrombin titers in the first group is 31 to 119 per cent of normal, with an average of 76 per cent. That in the second group is 14 to 76 per cent of normal, with an average of 45 per cent. In the first group, 8 of the 19 cases showed normal values, and only 4 had values below 50 per cent of normal, whereas in the second group none were normal and 10 of the

14 cases showed titers below 50 per cent. Thus, *Treatment.* At the beginning of the present study a few patients were treated by the oral ad-

*Plasma bilirubin in all cases gave the direct van den Bergh reaction bleeding after operation.

at an early stage, it is usual during the first four weeks to find normal or moderately low values, whereas after four weeks the titers are all low and the grosser deficiencies much more frequent.

ministration of bile only. This corrected the prothrombin deficiency, but the return to normal was slow. In Case 40, the prothrombin titer before treatment was 42 per cent of normal. After

days' treatment with bile salts it was 34 per cent, and later it gradually rose, reaching 75 per cent on the eleventh day of treatment and 116 per cent on the fifteenth day. In Case 5, the level of prothrombin before treatment was 68 per cent. After nine days' treatment with bile salts it had reached 105 per cent. In Case 8, the initial level was 24 per cent of normal. After five days of bile treatment it was 17 per cent; it then gradually rose, reaching 45 per cent on the twelfth day. On the evening of the twelfth day the patient had an injection of 2-methyl-1,4-naphthoquinone (Kapilon) and the next morning the prothrombin level was 64 per cent. After this, one more injection of the naphthoquinone was given; the prothrombin was not estimated again, but operation was performed without any hemorrhagic complication.

Early in the course of this study, treatment by intramuscular injections of 2-methyl-1,4-naphthoquinone was adopted throughout the hospital before operation and in the postoperative period, as well as for some patients who were not operated on. In obstructive jaundice the treatment regularly caused a rise in plasma prothrombin. In Case 29, the prothrombin level rose from 67 to 99 per cent; in Case 22, from 35 to 118 per cent; in Case 19, from 47 to 100 per cent; in Case 35, from 20 to 77 per cent; in Case 37, from 15 to 64 per cent; in Case 15, from 59 to 100 per cent; and in Case 42, from 27 to 76 per cent. The time required for full restoration varied, and in some cases estimations were not made frequently enough to show the rate of response. Where estimations were made at short intervals, they showed that some response was obtained very early. In Case 35, the plasma prothrombin level before treatment ranged from 19 to 21 per cent; four hours after the first dose of 1 cc. of Kapilon* it had risen to 34 per cent; the patient then received 2 cc. daily (except for an omission on the fourth day) and the level rose gradually to 77 per cent by the tenth day. In Case 37, the level before treatment was 15 per cent and seven hours after the first dose of Kapilon it had risen to 49 per cent. Case 42 showed a rapid response. The first observation was made when the patient was suffering from postoperative hemorrhage and the plasma prothrombin was 27 per cent of normal. At 11 a.m. on the following day she was given 1 cc. of Kapilon. At 4 p.m. there was still some oozing from the wound and the plasma prothrombin was 64 per cent. There was less oozing during the following night; the next morning the prothrombin level was 76 per cent and the hemorrhage was controlled.

*One cubic centimeter contains 5 mg. of 2 methyl-1-4 naphthoquinone.

In only 1 case of obstructive jaundice (Case 31) was the response unsatisfactory. Before treatment, the prothrombin titer was 42 per cent of normal. The patient was given 1 cc. of Kapilon daily; on the second day of treatment the prothrombin was 55 per cent of normal, and on the fourth day, 51 per cent. The diagnosis was carcinoma of the pancreas, and since there was enlargement of the liver and ascites, it seems probable that the lack of response to treatment was due to invasion of the liver by secondary growth.

Hemorrhage. None of the patients with obstructive jaundice showed spontaneous hemorrhage on clinical observation. There were 2 fatal cases, not suitable for operation, in which some hemorrhage without anatomic cause was found at autopsy. One of these patients (Case 46) had lymphadenoma, with obstruction to the pancreatic duct by lymph nodes, together with cholecystitis, gallstones and terminal acute pancreatitis. The plasma prothrombin level was 31 per cent of normal and there was hemorrhage from the gastrointestinal tract. The other patient (Case 11) had a carcinoma of the pyloric end of the stomach, with obstruction to the common bile duct and secondary carcinoma of the liver and lungs. The plasma prothrombin was 31 per cent of normal, and there was a hemorrhage into the pelvis of one kidney.

It is generally agreed that spontaneous hemorrhage occurs only with gross deficiencies in prothrombin, and that the main danger is postoperative hemorrhage. This was rarely seen in the present study because, with one exception, all patients showing low prothrombin levels, and several who had normal levels were given prophylactic and often postoperative treatment. In all, 53 cases of obstructive jaundice came to operation; only 7 had abnormal postoperative bleeding, and in 3 of these it was slight.

In Case 42, already mentioned, the prothrombin had not been estimated before operation and no treatment had been given. There was bleeding from the wound after operation, with the plasma prothrombin 27 per cent of normal. Treatment with naphthoquinone quickly restored the prothrombin level and controlled the bleeding.

In Case 16, the original level of prothrombin was 31 per cent of normal. The patient had a week's course of naphthoquinone injections before operation (cholecystgastrostomy), but no further prothrombin estimations were made before the operation. On the third day after operation there was slight oozing from the wound. The next day the plasma prothrombin was 65 per cent of normal; the oozing had then ceased.

In the other 5 cases with postoperative bleeding, the prothrombin had been found normal before operation, either without treatment or after treatment. In Case 10, the preoperative prothrombin level was 110 per cent of normal, and at the time of postoperative bleeding 62 per cent. Naphthoquinone was given at this stage and the bleeding controlled. In Case 13, the preoperative prothrombin level was 112 per cent of normal. No preoperative treatment was given, and bleeding occurred four days after the operation, with the plasma prothrombin 38 per cent of normal. The patient died. These cases confirm the observations of other workers that the prothrombin level may fall after operation and that a normal preoperative level does not exclude risk. The 3 other patients were known to have normal prothrombin titers before operation, but the estimation was not made at the time of bleeding. In 2 of them the oozing was only slight, and since both had chronic cholecystitis with adhesions, the cause may have been anatomic.

So far as can be judged from these few cases, it appears that postoperative hemorrhage is likely to occur when the plasma prothrombin is 60 per cent or lower.

Diseases of Liver

The results in 40 cases of liver disease are shown in Table 2. Of these, 27 showed deficiency in plasma prothrombin.

In acute or subacute hepatitis of various types (Cases 52 to 69, inclusive), the titers ranged from 17 to 106 per cent of normal. Seven out of the 18 cases showed normal results, and most of the remainder showed moderate deficiencies, only 3 having titers below 56 per cent of the normal average. None of the 3 cases of Weil's disease showed any gross hemorrhagic tendency; there were no hemorrhages in Case 69, only slight hemorrhages in the gums in Case 67, and slight purpura in Case 68. There was 1 case in this group with gross hemorrhage, namely Case 66. This patient had several courses of antisyphilitic treatment (arsenicals and bismuth) between December, 1940, and July, 1941. In October, 1941, he was admitted to the hospital severely ill and jaundiced and died on the day of admission from *Clostridium welchii* septicemia and peritonitis. There were extensive hemorrhages in the serous cavities, endocardium and intestines, and histologically the liver showed evidence of successive phases of toxic damage, attributable to the arsenical treatment. The plasma prothrombin level a few hours before death was 19 per cent of normal.

In 2 cases of liver atrophy (Cases 73 and 74), there was severe prothrombin deficiency, and in

2 cases of post atrophic fibrosis (Cases 78 and 79), there was considerable deficiency.

There were 12 cases of cirrhosis of the liver (Cases 80 to 91, inclusive). Only 3 of these showed normal prothrombin levels, but the deficiencies in the remainder were usually slight, the titer falling below 50 per cent of normal in only 2 cases.

In 15 of the 40 cases of liver disease, a levulose tolerance test was performed. When this test is based on analyses of blood levulose, the maximum normal rise is 15 mg per 100 cc and most normal subjects show rises of no more than 10 mg per 100 cc. Results in the range of 10 to 15 mg per 100 cc. may be regarded as borderline. In 3 cases (Cases 55, 58 and 86), the rise in blood levulose was less than 10 mg per 100 cc. The prothrombin titers were 80, 106 and 92 per cent of normal, respectively. Four cases (Cases 61, 65, 82 and 91) showed borderline results. The prothrombin titers were 86, 88, 70 and 73 per cent of normal, respectively. Of the cases with deficient levulose tolerance, 3 (Cases 62, 81 and 89) had moderately reduced tolerance, with rises of blood levulose of 15 to 25 mg per 100 cc. The prothrombin titers were 75, 72 and 113 per cent of normal, respectively. There were 5 cases (Cases 63, 64, 74, 84 and 87) showing gross deficiency in levulose tolerance, with rises of greater than 25 mg per 100 cc. The prothrombin titers were 53, 57, 36, 70 and 33 per cent of normal, respectively.

In this small series, therefore, the prothrombin fell below 70 per cent of normal only when the levulose test showed gross deficiency.

Effects of Treatment

Several authors have pointed out that hypoprothrombinemia associated with damage to the hepatic parenchyma does not respond to treatment with vitamin K or its analogues. The present study affords examples of this lack of response. One case (Case 31) has already been mentioned in which a poor response was attributed to secondary carcinoma of the liver.

In 5 of the cases listed in Table 2 the effect of injections of naphthoquinone was tried. In Cases 60 and 64 there was some rise in plasma prothrombin, but the jaundice was improving at the time and the rise in prothrombin may have been due as much to natural recovery as to treatment. In the other 3 cases (Cases 74, 85 and 87) there was no response. The first (Case 74) was a case of subacute liver atrophy with grossly deficient levulose tolerance. The initial level of plasma prothrombin was 36 per cent of normal, and after daily injections of naphthoquinone for twelve days it was 38 per cent. The other 2 (Cases 85 and 87) were cases of cirrhosis. The

levulose tolerance was not estimated in Case 85; it was grossly deficient in Case 87. In Case 85, 1 cc. of Kapilon was given daily for six days, and the prothrombin titers before and after treatment were 54 and 52 per cent, respectively. In Case 87,

similar to those obtained by Brinkhous, Smith and Warner²⁷ and by Stewart and Rourke²⁸ with the two-stage method, although there is a slightly higher proportion of normal results in the present series. The three series of results are not quite

TABLE 2. Summary of Data in Cases with Liver Disease.

*Plasma bilirubin gave the direct van den Bergh reaction in all cases except those described as normal.

2 cc. of Kapilon was given daily for seven days, and the prothrombin titer, 33 per cent of normal, was exactly the same before and after treatment.

SUMMARY AND CONCLUSIONS

The incidence of prothrombin deficiency in obstructive jaundice has been estimated by the two-stage technic in a series of 51 cases with serum-bilirubin levels over 2.4 mg. per 100 cc. Of these, 68 per cent showed hypoprothrombinemia, and in 30 per cent the titers fell below 50 per cent of the normal average. These results are closely

comparable, owing to differences in technic and in clinical material, but they do not differ greatly.

In 40 cases of liver disease studied in the present series, 68 per cent showed hypoprothrombinemia, and in 25 per cent the titers fell below 50 per cent. In some cases hypoprothrombinemia was found when the jaundice was extremely slight.

Cases are given of the restoration of the plasma prothrombin level to normal by treatment with 2-methyl-1,4-naphthoquinone in patients with biliary obstruction, and of the failure of this treat-

ment when there was damage to the hepatic parenchyma.

In common with other authors, it was found that patients with a normal plasma prothrombin before operation may develop hypoprothrombinemia and hemorrhage a few days after operation.

I am indebted to the honorary medical and surgical staff of the Royal Victoria Infirmary for the opportunity to investigate patients under their care and for the use of their clinical notes, and to my colleagues on the pathological staff for the use of their post mortem records.

VENOUS PRESSURE IN THE LOWER EXTREMITIES DURING ABDOMINAL OPERATIONS*

DAVID DAVIS, M.D.,† SAMUEL GILMAN, M.D.,‡ AND A. STONE FREEDBERG, M.D.§

BOSTON

THE frequent occurrence of postoperative thrombophlebitis of the femoral and leg veins makes it important to obtain data bearing on the state of the venous circulation in the legs during operation. Since such data are scanty it was decided to study the venous pressure in the leg veins during abdominal operations. Certain studies de-

minute intervals during abdominal operations. Following general or spinal anesthesia, these veins are usually prominent and admit an 18-gauge needle. A citrated 0.2 to 0.8 per cent solution of sodium chloride was used. Routine operative procedures were in no way altered during these observations. With each change in position, the

FIGURE 1. *Hysterectomy (spinal anesthesia).*

signed to elucidate the origin of the changes observed were also made.

MATERIAL AND METHODS

Studies were made in 18 cases. Ten patients had operations on the uterus, the procedures consisting of subtotal hysterectomy in 8 cases, panhysterectomy in 1 and presacral neurectomy with uterine suspension in 1; 4 patients underwent cholecystectomy, and 4 unilateral herniorrhaphy.

The venous pressure was measured by the method of Moritz and von Tabora¹ in one of the superficial veins of the foot at approximately one-

distance from the surface of the operating table at the heart level to the floor was measured and the angle of the table recorded. In the horizontal position, the point of reference was taken as 10 cm. above the surface of the table,² while in the Trendelenburg position the location of the left auricle was estimated. Using this estimated position as a point of reference, it was found that the manometer reading increased proportionally as the degree of the Trendelenburg position increased. According to Clark, Hooker and Weed,³ this increase is a hydrostatic effect due to the changing position of the true point of reference, which is no longer the auricle. The same change can be obtained in dead animals. In the present studies, therefore, only increases for a given position were considered significant. The position of the legs, whether extended or flexed at the knees, did not appreciably

alter the manometer reading for any given position of the table

OBSERVATIONS

Operations on the Uterus

Appreciable increases in venous pressure in the leg occurred during some stage of the ten opera-

tures at this period of the operation were generally close to the preoperative values, they were often slightly higher and at times, as noted above, considerably above the preoperative levels

In 8 of the 10 cases, the increases were of the same general magnitude, that is, 15 to 30 cm (Figs 1, 2, 5, 6 and 7) In 2 others (Figs 3 and

FIGURE 2 *Hysterectomy (nitrous oxide oxygen and ether anesthesia)*

tions on the uterus. In certain cases they were marked and prolonged (Figs 1-7). The first sharp change in the curve in 3 cases (Figs 1, 2 and 3) was due to a change in the base line following a shift from the horizontal to the Trendelenburg position. Rises above this level, however, represent true increases in venous pressure. Such increases sometimes followed the introduction of packs and exploration of the abdominal cavity, but this did not occur regularly. Marked rises in venous pressure, however, occurred in almost all cases when traction was placed on the uterus or its adnexa during isolation and ligation of the uterine and ovarian vessels. The rises generally persisted as long as the uterus was held ante flexed or under traction. The degree of tension that the surgeon was applying at a given moment could not, however, be estimated with accuracy.

The venous pressure generally fell sharply when traction on the uterus was released, although it did not always immediately return to previous levels. In 2 cases (Figs 4 and 5), the return to lower levels was gradual following amputation of the uterus. A similar elevation in venous pressure at the close of the operation is noted in another case (Fig 6). Although the venous pres-

sure at this period of the operation were generally close to the preoperative values, they were often slightly higher and at times, as noted above, considerably above the preoperative levels.

Cholecystectomy

In 2 of the 4 cases of cholecystectomy the venous pressure showed little change during operation. Appreciable increases occurred, however, in the course of the other 2 during exploration of the common duct, packing and various preparations for roentgenography (Figs 8 and 9). The application of the abdominal binder did not cause an increase in venous pressure.

Herniorrhaphy

In the 4 operations for herniorrhaphy, the venous pressure was measured in the veins of the foot on the side of operation. Few changes were noted. In one case, however, there was a marked increase at the time the conjoint tendon was sutured to Poupert's ligament. In another there were intermittent rises of 5 to 10 cm above the initial pressure.

The application of the adhesive dressing and abdominal binder at the end of operation was, however, accompanied in 3 cases by a persistent

increase in venous pressure of 3, 9 and 14 cm., respectively (Fig. 10). In the last case a rise of 5 cm. was noted when the dressing was applied, and with the application of the binder there was a further rise of 9 cm. This total increase of 14 cm. persisted for the thirty minutes that observations were permitted. Three hours later the venous pressure had returned to normal.

DISCUSSION

Veal and Hussey,⁴ in the course of ten abdominal operations performed for a variety of condi-

FIGURE 3. Presacral Neurectomy and Simpson Suspension (nitrous oxide, oxygen and ether anesthesia).

tions, measured venous pressure simultaneously in the antecubital vein of the arm and in the great saphenous vein close to its opening into the femoral vein. They were not impressed with the magnitude of the changes noted, although in 2 cases of hysterectomy there were maximum increases in the saphenous vein of 14 and 18 cm., respectively, above the preoperative level.

The data presented here, however, show far greater increases, particularly in the course of certain operations. The three types of operation selected for this study were chosen because the incidence of postoperative thrombophlebitis is different in each. In a recent study, for example, Barker,

Nygaard, Walters and Priestley⁵ found the incidence of postoperative thrombosis and embolism

FIGURE 4. Hysterectomy (ether anesthesia).

to be 4.1 per cent for abdominal hysterectomy, 2.1 per cent for cholecystectomy and 1.3 per cent for

tending the early... McLachlin¹¹ also... di... end of the cu... habit produces... ns. Franklin and... stimulation of the... nerve... e cat... of... or... from the present study, it appears that local veno-spasm is a possible factor in the rise in venous pressure obtained in the course of certain operations. If it is a cause of the increases noted, it is

important to know its duration. The increases obtained in our experiments often continued for thirty minutes or longer. The duration of the rise

in sixty to ninety minutes. This adjustment is probably the result of the opening up of collateral circulation and a general increase in the size of the

FIGURE 10 Effect of Abdominal Index after Repair of Unilateral Hernia

cannot be used as an indication of the duration of obstruction due to spasm. Thus, after a ligature is placed around the common iliac vein at its junction

vascular bed. Similar changes undoubtedly occur on obstruction to other vessels, and the slow fall in venous pressure observed in our experiments may

FIGURE 11 Diodrast Venograms before and after Stimulation of the Peripheral Cut End of the Sciatic Nerve in a Dog

tion with the venous cavity in a dog or a cat, the venous pressure in a leg vein rises rapidly to a level of approximately 120 cm of water, after which it falls slowly, reaching the previous normal value¹²

have a similar basis. Thus a normal or only slightly elevated venous pressure at the end of the operation does not exclude the continued operation of factors responsible for the antecedent rises

The rises in venous pressure following the application of a binder after herniorrhaphy are probably best explained by mechanical obstruction to the venous return at the anterior rim of the pelvis. Similar rises are obtained by applying moderate pressure directly over the femoral vein in this region. Whatever the mechanism, the importance of avoiding a tight binder is apparent.

SUMMARY AND CONCLUSIONS

Marked increases in venous pressure were observed in the veins of the foot in the course of operations on the uterus and its adnexa. Less striking changes were noted during cholecystectomy and inguinal herniorrhaphy.

The possible role of local venospasm in the production of these increases is discussed.

BOSTON MEDICAL LIBRARY

REPORT OF THE PRESIDENT*

THE year 1942, included with the month of December, 1941, the first thirteen months of our participation in World War II, has had the expected and inevitable repercussions on the Boston Medical Library, increasing our expense, diminishing our income, posing new difficulties of administration and interfering seriously with the work of our librarian and our director in maintaining the normal flow and use of medical literature. The Trustees voted to remit the dues of fellows who entered active service with the colors; resignations, presumably owing to difficult economic conditions, increased in number; and thus our income from dues decreased by \$497 as compared with 1941. Income from investments was \$12,984 as compared with \$14,922, a decrease of \$1938, and in spite of rigid economies our operations showed a deficit for the year of \$1305.91. On March 16, 1942, the Trustees voted an increase of 10 per cent in the salaries of our small and devoted staff, to meet at least in part the increased cost of living.

The most unexpected administrative problem that arose during the year was the necessity for meeting the situation created by the sharp limitation of the oil available for our heating plant. The Oil Rationing Board, in December, 1942, announced that they could promise us only enough oil to keep open for one week during each month. It was impossible to change from oil burners to coal-burning grates without a prohibitive expen-

diture, and the problem was solved—I hope successfully—by contracting with the Boston Edison Company to make suitable installations and supply steam for heating. With this assurance of our purpose to co-operate, the Oil Rationing Board promised enough oil to enable us to carry on until the conversion is completed. The cost to us of this installation, the increased cost of heating and a statement of its efficiency will be subjects for the next annual report.

An anniversary of great significance to us was the semicentennial of the entry of our director, Mr. James F. Ballard, into the service of the Library. On October 24, 1892, as a boy of fourteen, he applied for work to Dr. Brigham at the modest little home of the Library on Boylston Place. Beginning then as a stack and errand boy he has served us continuously and efficiently ever since, educating himself in the technic of library administration and acquiring a familiarity with medical literature and a knowledge of medical bibliography that has placed him in the front rank of medical librarians in this country and won him the position of director of the library. The Trustees voted to establish and solicit contributions for the James F. Ballard Publication Fund, with which it is hoped to issue from time to time items that will make better known to its friends the treasures and resources of the Library. In his report as librarian Dr. Viets tells of the proposed publication of the first of these issues, *A Catalogue of Medieval and Renaissance Manuscripts and Incunabula in the Boston Medical Library*.

*Read at the annual meeting of the Boston Medical Library, March 2, 1943

The policy to be pursued in shaping the course of the Library to the end that it shall be increasingly prosperous and useful to the profession, and thus to the public, has continued to receive the earnest consideration of the Trustees. In the annual report for 1941 note was made of a survey, whose cost was defrayed by the Carnegie Corporation, of the resources and inter-relations of the various collections of medical books and periodicals in Boston and its vicinity. It will be recalled without going into details that this report urged that the Library be developed in the future, as in the past, as a reference and research library, supported morally, and if possible financially, by the lesser libraries of medical schools and hospitals, whose working collections would be supplemented by loans and exchanges from our own. During the past year meetings were held by representatives of the Library, of Boston University, Tufts and Harvard medical schools and of various hospitals to discuss the matter, and a substantial agreement of principle was reached without the disclosure of actual ways and means. An informal subcommittee has continued to study the matter. Especially helpful and full of suggestions has been Mr. Keyes D. Metcalf, director of the Library of Harvard University, who, after surveying our building, equipment and collections, was positive in his recommendation that our aim should be to complete our stacks, finish and furnish the periodical reading room, improve the conveniences of Holmes Hall and, last but not least, increase and strengthen our overworked staff. In his opinion the Library could thus be made adequate and convenient for the ensuing twenty-five or thirty years.

What would be the approximate cost? Before the war, the estimated cost of five new tiers of steel stacks was \$70,000; the appropriate finishing and improvements in the periodical reading room and Holmes Hall might require \$15,000, and a capital sum to yield an income of \$10,000 would take care of the enlargement of our staff, of neglected binding and rebinding and of useful development of our services to the community. There are surely farsighted and generous persons who can be helped to see the far-reaching importance of medical library facilities to Boston and New England and who would include us with the hospitals and other charitable institutions that they propose to support by gifts and bequests. A gift may be designated for some special purpose as a memorial or otherwise, or given as a capital sum whose income shall be spent for some indicated purpose or, better still, a gift or bequest may be free of all restrictions, to be used at the discretion of the Trustees. The generous support by New England people of all forms of education is traditional. Is it too much to believe that some of our 800 fellows will be able to convince prospective donors of the privilege that is offered them in bringing to their notice the needs of the Boston Medical Library?

Lest we forget, it should be added that those of us whose imaginations take flight occasionally among the nebulae, still dream of the tax-harassed plutocrat of the future, who may find surcease from his cares in endowing a splendid academy, built about the collections and perpetuating the name of the Library.

DAVID CHEEVER, *President*

REPORT OF THE LIBRARIAN*

IT IS again the privilege of the librarian to bring to the attention of the members of the Boston Medical Library a report on the Library for the year 1942. We have continued along lines similar to those in the past with surprisingly little change in view of the war conditions. Chiefly, we have been forced to curtail some of our services, and the hours of opening have been abbreviated to a marked extent. Toward the close of the year it was necessary to give up opening in the evenings, and finally the Library had to close its doors as early as three o'clock in the afternoon. This was a considerable hardship, for our members were greatly restricted in regard to the time when they could draw books from the Library or visit the building itself. Our visitors,

moreover, were inconvenienced, since many of the students formerly used the Library in the evening. Thus our attendance fell off from the 1941 figure by about 2500, reducing the total number of people who came to the Library to less than 10,000 during the year, a reduction that has not occurred during the previous five-year period.

There was, in consequence of this, a decrease in circulation, but not so much as one might expect. Over 33,000 volumes or pamphlets were taken from the shelves during the course of the year, thus maintaining about the rate of 10 per cent of the total books and pamphlets in the Library that are in use each year. The total holdings at the end of the year were over 325,000 items, there being a gain of about 2500 books. This is our normal rate of increase in recent years, al-

*Read at the annual meeting of the Boston Medical Library, March 2, 1941.

though not so large as formerly. The loss, however, is not mainly in books, but in foreign periodicals. The figure in 1940, when we added more than 1500 bound periodicals, can be compared with slightly over 650 in 1942. The chief loss in the periodicals is in the complete absence of French and German journals, which were formerly a considerable part of our yearly gain. To compensate for these, however, we have added a few new American journals, and the English journals are still received in nearly a normal amount. We have added only a few books to the special collections, thus putting most of our emphasis on new books and current periodicals. This, we believe, is in trend with the times, for there is an active interest in all that is new in medicine and to supply this need is the duty of a library such as ours. It is interesting to note, moreover, that our inter-library loans are an increasing part of our service and that we are now supplying, in addition to the ordinary demands from various libraries in New England, the Army and Navy centers as well as important munitions plants. Calls came, for instance, during the year from the General Hospital at Fort Banks in Winthrop, the Fort Devens Service Club, the Lovell General Hospital at Fort Devens and the United States Veterans Administration at Bedford. In addition, books and journals went to the Edgewood Arsenal for the United States War Department, the National Fireworks, Incorporated, and E. I. du Pont de Nemours and Company, Wilmington, Delaware. Thus, it would seem that our library is appreciated both by our members and neighbors, and by those who live some distance from us. We may modestly state, moreover, that we are doing our share in the war effort and supplying those who ask for our services.

A number of events of considerable importance to the Library occurred during 1942. In the autumn, Mr. Ballard, the director, completed fifty years of service to the Library,* and in his honor a reception was held, attended by many of his friends. In addition, he received many congratulatory letters and other evidences of esteem. In writing to the librarian on this occasion, Mr. H. U. Holzer, whose firm, U. Holzer, Incorporated, founded by his father, has bound books for the Library since about 1875, recalls some of the early days when he, as a boy, began to follow in his father's footsteps.

My first recollections of Boylston Place are very strong with me today. I have a very vivid feeling of the old place, the meeting room, which seemed to me

an awesome cave; walls, stairs, landings, rooms, closets, all lined with books, and the heartening presence of Dr. Brigham, who was the most invigorating personality I have ever known. It all blends into an integral part of that time of my life.

In August, 1888, I carried my first load of books from Boylston Place to Bromfield Street, in a small wheelbarrow, inherited from my small-boy predecessor. The whole distance was paved with round cobblestones,—and to a small country boy's self-consciousness, even a small wheelbarrow can seem to fill the air with clatter,—from Cambridge to South Boston.

It did not take long before I learned to transfer the laceration from my pride to my body, by carrying what the wheelbarrow would hold on my shoulder.

By the time Mr. Ballard entered the service, transport was in the hands of my successor, who, being city-bred, was not bothered by the clatter of the wheelbarrow. It was therefore somewhat later that I made Mr. Ballard's acquaintance, and we became James and Henry, and began to travel down the years together.

Presently we were chartering a horse and team for deliveries and pickups, and by 1912 gasoline displaced oats for our transportation. I hope and trust that we may not have to revert to the wheelbarrow.

Fifty years! Sixty years! The length of my definite memory of this city. What they have wrought to Boston Medicine!

In the earliest days my godparents occupied a cottage on Longwood Avenue, exactly where the Richardson House, of the Boston Lying-in Hospital now stands. For a coincidence, Dr. Richardson was the first human to set eyes on me.

Opposite the cottage, from Longwood Avenue to Francis Street and from Huntington Avenue to Vila Street, was an apple orchard, and where the Peter Bent now stands I have played three-o-cat. I suppose Peter at that time was in full cry after the dollars with which to transform that land.

Behind the cottage, as far as Massachusetts Avenue, was only marsh and creek, where we children skated and ran teets when I visited on winter days. Not one of the great assembly of institutions now there existed except in dreams. What about other parts of the city? In the region about Tufts Medical, was, first, a great exhibition building, which burned, a series of animal circus stands and a Fall of Pompeii spectacle, all long since departed.

At the other end of the city, so far as I can remember, the Bulfinch Building contained all there was of the Massachusetts General Hospital. Today there is a medical metropolis round about it.

Dr. Maurice Richardson used to come into the shop and tell my father that he thought there must be some books ready for binding at the Treadwell Library. Father would go down and gather up the periodicals from table and closet, making up complete volumes, and chasing up missing numbers, later sending me down to get them with the accursed wheelbarrow. It seems to me that my father was the only acting librarian. Since then, first Mrs. Myers, then Miss Williams, each have put in years as full-time librarians, and now Miss Lewis is in charge.

In the very first days of my working, there came into the shop a little smiling young lady, with an irresistible manner, asking for dollar contributions for the

*Recognition of the occasion was noted by the *New England Journal of Medicine* (227:610, 1942), the *Journal of the American Medical Association* (120:626, 1942), the *Bulletin of the Medical Library Association* (31 iv, 1943) and others.

Boston Dispensary. Annually, for years, she reappeared, and on her face we could see the passage of time, as she gathered wrinkles, as well as dollars, until at last she was quite an old lady.

Today, gathered about the little dispensary, which asked for dollar contributions, is the Joseph H. Pratt Hospital, the New England Medical Center Building and I know not what extensions.

What about the Harvard Medical School? Full many a trip did I make to 688 Boylston Street to get books from the professors: Bowditch, Wood, Harrington, Ernst, Councilman and others. Their personal checks paid the bills. They had all made their studies in Germany, and were well disposed toward the Swiss bookbinder, who knew so many languages, and whom they met at the Orpheus Musical Society, where he was active.

Since those days, the great school buildings have arisen, with the professional librarians, the great central library and the various department libraries—all these on that same old apple orchard of my boyhood.

Verily, I shall soon believe that out of little acorns, great oaks do really grow.

Besides this, on every hand, hospitals, and more hospitals, with libraries that appear on our ledger.

As to individual doctors: On how many a slobby night have I left burdens on their doorsteps!—Bush, Bowditch, Holmes, Hays, Blake, Roteh, Chadwick, Farlow, Minor, Wesselhoeft, Hontans, Warren: a host and yet a host.

Secondly, Mr. Ballard has prepared for the Library a catalogue of its medieval manuscripts and incunabula.¹ This has been a congenial task for him, for the collation of these precious books has been one of his prime interests for many years. Beginning with a few books left to the Library by Oliver Wendell Holmes, the Collection has grown through the purchases from the John Warren Fund and the large and valuable collection of incunabula assembled by Dr. William Norton Ballard, to which have been added many more through funds left by Dr. Ballard at the time of his death in 1931. With the manuscripts of Jewish medicine, bought through the Geoffrey M. Hyams Fund, we now have more than 700 manuscripts and incunabula in the Library. It seemed fitting to the Board of Trustees that Mr. Ballard, at this time, should make such a catalogue, and it has been the pleasure of the librarian to assist him in checking some of the items and aiding in the publication. A note from the introduction to the book by the librarian will give the members some idea of the size and importance of this collection.

A general impression of the contents and scope of the collection may be obtained by checking the Catalogue with Klebs's well-known short title list, *Incunabula Scientifica et Medica*. Over one thousand titles and three thousand editions are given by Klebs. Of the various classifications, the largest is medicine, with eight hundred and fifty editions. Of these, this Catalogue lists a rich store, the first and in many cases

other editions of Hippocrates, Galen, Rhazes, Abulcasis, Avicenna, Maimonides, Brunschwig and Ketham. In addition, Plato, Averroes, Aristotle, Pliny, Ptolemy, Alfraganus, Albumasar, Rabanus Maurus, Haly Abbas, Guy de Chauliac, Regiomontanus, the *Gart der Gesundheit*, Bagellardus and Germonius are well represented. There is a goodly list of the works of Albertus Magnus, a considerable number of almanacs, the writings of Beroaldus, Ficinus and Trithemius, the rare *Lehre und Unterweisung* and a few examples of the *Regimen Salernitanum*. George Sarton, in illustrating his long review of Klebs's *Incunabula Scientifica et Medica*, chose forty-nine books, "to give the reader a fairly good idea of the scientific incunabula." If this is used as a check, first eliminating some of the books in other fields than medicine, thirty-one titles are left to be considered. The Boston Medical Library collection contains, of the thirty-one, twenty first editions and five later editions. Of the remaining six, four are so rare that it is unlikely that copies will ever be available. Thus, the collection is reasonably well rounded out, not lacking in any particular field. The scholar will find some edition in the Library of nearly every book of medical interest published before 1501.

The third event of importance was the restoration of a valuable portrait in the Library. For some years we have owned a portrait of Samuel Danforth (1740-1827), Paul Revere's physician and one of the founders of the Massachusetts Medical Society. In connection with the Revere Exhibit at the Museum of Fine Arts in the fall of 1942, the Danforth portrait was sent to the Museum. There the picture was cleaned and, much to our surprise, it was found to be an exceptional example of the great art of Gilbert Stuart. It is even considered by some as one of the best portraits ever painted by Stuart, and thus the Library contains a rare and exceedingly valuable picture. The trustees of the Museum of Fine Arts gave it an important place in their exhibit, and added publicity came through the publication of a book, *Paul Revere and the World He Lived In*,² by Esther Forbes at about the same time. The portrait is of a man of handsome features, exquisitely delineated by the artist.

In addition to these three important events, the librarian would again call attention to the varied interests of its members. We have to collect on a wide base, for difficult it is to predict what interests the persons who use our library may have. Samuel Eliot Morison,³ for instance, in writing his life of Christopher Columbus, wishing to include a chapter on syphilis, turned to us for the pertinent material. In addition, during the past year there has been an increased use of our rare books, particularly the manuscripts and incunabula, by scholars both here and from a dis-

¹A chapter, "The Sinner Shepherd," in the second volume, contains a list of the names of the various persons who have been the subjects of the hypnagogic sketches. ²Indian captives. ³Grand Journal of

tance. Our own members, too, are beginning to use our library as only a librarian could wish for them to do. Their interests, as I have noted above, are indeed almost as varied as that of the great John Hunter and his wife. Mrs. Hunter was a most charming and accomplished woman who was particularly fond of music. Haydn was one of her close friends and, indeed, she wrote the words for Haydn's great classic, *The Creation*, and for at least a dozen of his songs. John Hunter, however, was interested in Haydn for quite another reason; for Haydn is said to have been the possessor of a particularly fine nasal polyp, and the story goes that Hunter tried to remove this without the owner's consent.⁴

Whether you are interested in the latest research on polyps or, indeed, in music, the Library tries to supply your wants. Only recently there have come to hand two examples of the verse of Oliver Wendell Holmes set to music. One is the rare "Battle of Lexington" and the other the "Ballad of the Oysterman." We have not forgotten, therefore, that someone might be interested in music, and thirty-six pieces by physicians or distinctly medical in character were added to the Library in 1942. We have tried, moreover, to supply the latest information about nasal polyps, and do the best we can to keep up with the times by furnishing you with the current texts and periodicals. For the texts, in large part, we are indebted to the *New England Journal of Medicine* and the reviewers of these books who so generously donate them to our shelves.

Of the special accessions to the Library, I need only mention one or two. To the early printed-book collection we have added an Augsburg almanac for 1470, one of the earliest of its type. A fourth edition of the *Fasciculus Medicinæ* by Ketham completes our collection of this fundamental work. To our American account books we added one kept in the late eighteenth century by Nathaniel Saltonstall of Haverhill, Massachusetts. Our early English imprints, now one of our main interests, have been increased by more than a dozen items.*

*Details of recent accessions will accompany the author's reprints. Copies may be had at the Library.

As usual, we are indebted particularly to our friends, both past and present, for large collections of books and periodicals. From Mrs. Frederick T. Lord was received Dr. Lord's library, and many books have been given by Dr. William C. Quinby, Dr. E. Stanley Abbot, Dr. James L. Gamble and others. Further installments of foreign medical dissertations and theses, in exchange for our public-health items, have been received from the Harvard Medical School. From Dr. Horace Binney, the Library came into possession of the medical chest of Dr. Barnabas Binney, of Philadelphia, a surgeon in the American Revolution. To these donors and others, the Library is indeed grateful.

Most changes in the Library that have been long contemplated have been held in abeyance for the duration of the war. We should not forget, however, our primary aim as an individual institution, namely, that we become the natural repository for books and other items of medical interest in Boston and its vicinity. Moreover, we hope to make closer and firmer, as time goes on, our relations with our sister institutions, in the meantime keeping our status as a distinct part of New England life. To the Boston Medical Library, one should naturally turn first for all books of medical interest. If we should not be the fortunate possessor of some desired book or pamphlet, the staff will make every effort to serve you by procuring this book as rapidly as possible. For failure to serve you quite as completely as we have in the past, we offer no apology. It is too obvious that we also are part of the war effort, and that adjustments must be made to the insistence of the world conflict.

HENRY R. VIETS, *Librarian*

MEDICAL PROGRESS

ADVANCES IN MALARIA RESEARCH

QUENTIN M. GEIMAN, Ph.D.*

BOSTON

MALARIA has been and still is one of the great medical enigmas of the world. The discoveries in the late nineteenth century and in the early years of this century gave great promise of providing the necessary information for the control and eventual eradication of this disease. This utopian achievement has not taken place, and it is now realized that new approaches and methods are needed to control malaria as it exists today, let alone eradicate it. Even the impetus given to malaria research by Wagner-Juaregg¹ in 1917, when he established the value of induced malaria in the treatment of parietic patients, and by the development of the synthetic antimalarial drugs, atabrine in 1933 by Mauss and Mietsch² and plasmochin in 1927 by Schulemann et al.,³ has failed to aid materially in reducing the tremendous yearly toll in morbidity and mortality caused by the disease.

The significance of this fact is well recognized by malariologists, medical entomologists, sanitary engineers and medical officers who have the job of controlling malaria in tropical and subtropical, endemic and hyperendemic malarious areas. Since the troops fighting for the Allied Nations in World War II are scattered throughout the malarious areas of the world, malaria control has assumed an extremely important position in the strategy of the war. Simmons⁴ has reviewed the scope of the problem and has given an account of the comprehensive program placed in operation by the Army to control malaria among our troops. It is quite obvious that the sum total of present knowledge is being utilized and applied in this program to prevent the occurrence of a serious malaria epidemic such as the opposing armies experienced in the Macedonian campaign during World War I.^{5,6} The effectiveness of this campaign has yet to be determined, but it is no idle prediction to state that failure of the program as planned can result only from a lack of basic knowledge and of trained personnel.

A potential malaria problem is facing the country as a whole. In World War I, relatively few of the military forces of the United States were en-

gaged in active service in endemic malarious areas. In this war, however, the majority are or will be engaged in such areas. Troops will come home on leave, will be invalidated home, and will eventually be discharged from the service after having served in malarious areas. Actually this is not only a malaria problem but a problem involving many diseases found in subtropical and tropical climates. Furthermore, this is not only a problem for the future but one for the moment. In New England, there have been cases of malaria among soldiers returning from maneuvers in the South, and a few British and American seamen coming into the port of Boston direct from Africa have had malignant tertian malaria and have been treated here.

Consequently, the purpose of this article is not to present a comprehensive review of malaria research, but to point out those contributions that will help in making a prompt and accurate diagnosis of malaria, to discuss the newer knowledge of pathogenesis and physiology of malaria, to consider the current conception of immunity in malaria, and to review briefly the value of anti-malarial drugs for treatment and prophylaxis.

SPECIES OF MALARIAL PARASITES

Malaria is commonly referred to as a single disease entity, but actually four infections produced by four different species of parasite are involved: tertian malaria, caused by *Plasmodium vivax*; malignant tertian (estivo-autumnal or sub-tertian) malaria, caused by *P. falciparum*; quartan malaria, caused by *P. malariae*; and ovale tertian malaria, caused by *P. ovale*. The geographical distribution, incidence and nature of these infections and the morphology and differential diagnosis of the parasites are thoroughly presented in available textbooks and manuals.⁷⁻¹⁴

Benign and malignant tertian malaria are the outstanding and most widespread infections. Quartan malaria, although of importance in Central Africa and parts of India, has a decided tendency to involve certain local and isolated areas. Infections with *P. ovale*, discovered and described in East Africa by Stephens,¹⁵ are very mild and are also rare. There are some doubts about the validity of this species, but the persistence of distinctive morphology after repeated passage

*The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 676 pp. Springfield, Illinois: Charles C Thomas Company, 1942, \$5.00).

¹Instructor in comparative pathology and tropical medicine, Harvard Medical School and Harvard School of Public Health.

through insect and human hosts, together with immunologic and clinical differences,^{16, 17} has helped to establish the species on a firm biological basis.

The use of induced malaria for the treatment of general paralysis of the insane has not only established the therapeutic value of the procedure, but has provided malariologists with an experimental method and host. Clinical malaria may be studied under controlled conditions, and abundant material may be obtained for study both from the human host and from anopheline mosquitoes infected by feeding on patients undergoing treatment.

The most significant advances obtained from the study of induced malaria have to do with the specific validity of the four species of malarial parasites and the discovery of different races or strains of parasites within a given species. The latter discovery has been of great value because it has helped to explain various problems of host susceptibility and immunity. These are discussed below; at this point, it is sufficient to say that these strains can be recognized by their virulence, antigenicity, infectivity for mosquitoes and reaction to quinine and other drugs.

Another source of evidence is the study of avian and simian malaria. Contributions from the laboratory study of avian malaria were stimulated by the discovery of the life cycle of the parasite in *Culex* mosquitoes by Ross, after he had found pigmented cysts on the stomachs of dappled-winged mosquitoes.¹⁸ This type of malaria has also been extremely useful in testing antimalarial drugs. The description of *P. gallinaceum* by Brumpt¹⁹ and its subsequent use by Indian and American workers for studies in immunology have opened a new approach to the subject. The simian parasites, *P. cynomolgi*, *P. inui* and *P. knowlesi*, have also been used experimentally with profit. The discovery of *P. knowlesi* in *Silenus irus* by Sinton and Mulligan²⁰ has greatly aided the advance of knowledge. When this parasite is inoculated into the rhesus monkey (*Macaca mulatta*), an infection develops that, if untreated, usually ends fatally in six to ten days after onset. The particular attribute of this species and also of *P. gallinaceum* is the high percentage of parasitized cells that develop during the later stages of infection (*P. knowlesi* 30 to 75 per cent, *P. gallinaceum* 30 to 80 per cent). Thus, for the first time heavy concentrations of parasites may be obtained for physiologic and immunologic studies.

LABORATORY DIAGNOSIS

Morphologic Diagnosis

When one recalls the great variety of clinical symptoms produced by cases of malaria, the vari-

ous atypical states of infection and the absence of symptoms in latent malaria, it becomes clear why a diagnosis of malaria is entirely dependent on finding and identifying the parasites in the blood. Through lack of facilities and of a proper technic and skill in detecting the plasmodia in blood films, the general practitioner and clinician too often neglect this essential procedure.

The current laboratory methods of preparing thin and thick films and of staining them satisfactorily have become simplified enough to be mastered by anyone with some facility and experience in microscopical technic.¹³ The practitioner should at least know how to prepare satisfactory films for shipment to a state laboratory or to a medical school for examination, if the procedures and examination cannot be performed in the private laboratory.

The technic of preparing thin blood films and staining them with the Romanowsky stains (Wright's, Leishman's or Giemsa's) is commonly known. Repeated studies have shown that the thick-film technic is advantageous for the discovery of a lower concentration of parasites and for saving time in performing the examination.¹³ The thick-film method is one of concentration. A large drop of blood is placed on a thoroughly clean slide. With the corner of another slide, a needle or other instrument, the drop is spread so that the red corpuscles are several layers thick in the center, tapering off to a single layer at the margin. The film should dry flat, and when it is dry one should be able to read print or see the hands of a watch through its thickest part. Before staining, the film should be placed in an incubator at 37° C. for one hour or kept at room temperature overnight.²¹ It should not be heated or flamed, because the cells will thus be fixed and dehemoglobinization of the red cells will be prevented. The film should be stained within forty-eight hours because of degenerative changes that take place in the drop, preventing differentiation in staining.

Dehemoglobinization of the red cells and staining of the parasites is carried out simultaneously in a 2 per cent Giemsa solution for forty-five minutes, or in a 10 per cent Wright-Giemsa solution for ten minutes.²² American-made (National Aniline and Chemical Company) Giemsa and Wright's stain can be used to make the required stock solutions. Only neutral or buffered water should be employed for diluting the stock stain, in order to ensure uniform results and also to prevent precipitation of the dye. Preparation of the buffered water can be carried out by the method of Field and Le Fleming²³ or that of Wilcox and Logan.²⁴

Field and Le Fleming's method Dissolve 0.55 gm of anhydrous disodium phosphate (Na_2HPO_4) and 0.4 gm of potassium acid phosphate (KH_2PO_4) in 1000 cc of distilled water (if $\text{Na}_2\text{HPO}_4 \cdot \text{H}_2\text{O}$ or $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ is used the quantity must be recalculated). This solution should have a pH of 7.0-7.2. If a different pH is desired the quantities of the salts are varied according to 5 molar sodium buffer standards.

Wilcox and Logan's method M/15 Na_2HPO_4 (95 gm of the anhydrous salt per liter) and M/15 $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ (92 gm per liter) or M/15 KH_2PO_4 (90 gm per liter) are mixed in the following amounts: the final volume being made 1000 cc by the addition of distilled water. pH 7.0-6.11 cc of the former and 38.9 cc of the latter, pH 7.2, 72.0 cc of the former and 25.0 cc of the latter.

Wright-Giemsa stain¹³ Dissolve 2 gm of Giemsa powder in 100 cc chemically pure glycerin from a fresh ly opened bottle with the aid of heating in a water bath at 55 to 60°C for two hours. Precaution must be taken to avoid absorption of moisture during the process particularly when the mixture is stirred. To this solution add 100 cc of aged Wright's staining solution (2 gm of Wright's stain in 1000 cc of chemically pure methyl alcohol). Let stand overnight then add 800 cc of aged Wright's staining solution. Filter.

A thorough knowledge of the morphology of malarial parasites must be acquired before attempting to make a microscopical diagnosis. The stained thin film is the method of choice for studying the typical morphologic characteristics of malarial parasites, and for the novice this is the best method for differential diagnosis. Nevertheless, the thick film technique is preferable for the reasons already given. Experience in thick film examination is necessary, however, before one can make a reliable diagnosis from it. Since from ten to fifty times more blood can be examined on a thick film than on a thin film in a given amount of time, the method should be mastered and utilized by all workers called on to make frequent or occasional blood examinations for malarial parasites.

A differential diagnosis of species should be established in all cases of malaria. A patient with malignant tertian malaria obviously requires more careful handling and treatment than does one with benign tertian infection. Finally, information concerning the previous use of antimalarial drugs should be obtained from each patient at the time blood is taken for examination. These drugs lead to the quick destruction and developmental inhibition of the parasites in the peripheral blood and may result in failure to find the parasites. Whenever there is any doubt and whenever possible, successive blood films should be taken at suitable intervals during at least two or three days to determine the existence of infection and to arrive at the correct differential diagnosis.

Serologic Tests

Since both chronic and latent malaria often exist without detectable parasites in the peripheral blood serologic tests is supplementary diagnostic procedures have held out a great deal of promise. Efforts to devise successful tests were greatly handicapped by the inadequacy of antigens prepared from infected human blood which has a relatively low density of parasitized cells.

The availability of several species of simian parasites particularly *P. knowlesi*, led to the following significant studies on the immunology of malaria. In 1935, Coggeshall and Eaton¹⁴ were able to demonstrate complement fixing antibodies in rhesus monkeys with a chronic *P. knowlesi* infection, using *P. knowlesi* antigen. Later Eaton and Coggeshall¹⁵ used the same test to study serums from human infections with *P. knowlesi* and with *P. vivax* and *P. falciparum*. Strong complement fixation was obtained with the three types of serum. Thus the reaction was shown to be a group reaction rather than a specific one.

This test has now been applied by Dulaney and Stratman-Thomas¹⁶ and Kligler and Yoeli¹⁷ to test serums from human cases of malaria in an effort to determine the value of the procedure for practical diagnostic purposes. In a later paper, Dulaney, Stratman-Thomas and Warr¹⁸ have shown that the test is highly specific for malaria, and again that it is group specific. They report 102 positive reactions (82 per cent) with serums from 125 patients who had demonstrable malarial parasites in their blood at the time serum was taken, 15 positive reactions (9 per cent) of 192 presumably malarious patients with negative blood films, and 24 positive reactions (14 per cent) in a group of 170 presumably nonmalarious patients who were suffering from bacterial or other protozoan diseases. Serums from syphilitic patients with no malaria gave no higher percentage of nonspecific malarial reactions than did normal serums.¹⁹ Kligler and Yoeli¹⁷ examined 309 serums obtained in a hyperendemic area, with 98 per cent positive reactions in children under twelve years and infected adults. Healthy adults gave 10 per cent positive reactions. Kligler and Yoeli also showed that serums of persons given repeated treatment react according to the interval between the last attack and the date of onset. Dulaney and Stratman-Thomas have pointed out that early treatment inhibits the development of complement fixing antibodies. The test appears to have practical use for epidemiologic purposes²⁰ but the reaction is more valuable as a supplementary test than as a substitute for the examination of blood films.²¹

In 1938, Eaton³⁰ demonstrated the presence of agglutinins in serums from monkeys with a chronic infection of *P. knowlesi*. Within the limits of the work, the agglutination reaction was specific, giving positive results only when a homologous combination was used. The observation that normal red cells and cells with immature parasites did not agglutinate in antiserum offers a basis for explaining the slow humoral response in antibody production and the activation of the lymphoid-macrophage system for cellular defense in the host. Because of the low density of parasites in human malarial infections, no similar tests have been performed with human malarial parasites and immune serums.

An important series of contributions was initiated in 1940 by Mulligan and Russell³¹ when they demonstrated the specific agglutination of sporozoites of *P. galinaceum* by dissecting salivary glands of infected mosquitoes in homologous antiserum in dilutions as high as 1:8000. Mulligan, Russell and Mohan,³² working with sporozoites and immune serums from human, fowl and sparrow malaria, presented strong evidence for the specificity of the reaction. Sporozoites of human malaria were agglutinated in a titer of 1:4000 by serums from chronic human cases. Sporozoites of sparrow malaria, *P. praecox*, were agglutinated in the extraordinary high titer of 1:8000 to 1:65,000 when chronic homologous serum was used. Cross-agglutination was observed in some cases to a titer of 1:128, indicating a slight group reaction. Although the method has possibilities for application to the diagnosis of human malaria, practical difficulties in providing and maintaining a supply of infected mosquitoes will no doubt prevent its adoption.

A precipitin test was devised by Taliaferro and Taliaferro³³ in 1928 in which an extract of human placenta from a case of malaria was used. This work has not been applied practically because of the scarcity of infected placentas for making the required antigen. The majority of workers with simian malaria have failed to get positive results. Dulaney and House³⁴ have been able to obtain a precipitative reaction with an antigen from *P. knowlesi*. Both the collodion-agglutination method of Cannon and Marshall³⁵ and the collodion-fixation procedure of Goodner³⁶ gave positive results. Macroscopic agglutination was obtained by both precipitative methods.

Skin tests have been devised for malaria, but the results do not seem to be consistent or significant. Hermann and Lifschitz³⁷ worked with human malaria, and Sinton and Mulligan³⁸ with monkey malaria. Stratman-Thomas and Dulaney³⁹ failed to repeat the above positive results and

stated that the reactions obtained did not fulfill the criteria for a delayed type of intradermal reaction.

Chemical Tests

Although the ferro-flocculation and melano-flocculation tests of Henry^{40, 41} were claimed to be specific antibody-antigen reactions, extensive studies have shown that this is not the case. The positive results obtained with serums from cases of malaria are dependent on an altered ratio of serum proteins. For this same reason positive tests were obtained by numerous other workers in a wide variety of diseases, such as typhus, kala azar and Weil's disease.^{42, 43} The pigments acted as indicators and not as antigens.

With the explanation available for the mechanism involved in Henry's reaction, Proske and Watson⁴⁴ developed a protein-tyrosin reaction to make a quantitative chemical estimate of the amount of euglobulin present in the serum from patients with malaria. The test is no more specific than Henry's reaction, but is much simpler. The reaction and results have been confirmed by at least one group of workers.⁴⁵

PATHOGENESIS

No generalization can be made about the course and severity of malarial infection without qualifications regarding the kind of malaria involved, the area in which the disease was contracted, and whether the malaria was naturally acquired or induced. It is true that tertian and quartan malaria have more constant courses than has malignant tertian malaria, which is very variable in its clinical manifestations.

The human malarial parasites are generally considered as well-defined species, but actually, as shown below, there are definite morphologic and physiologic differences between strains of the same species obtained from different malarious areas.

Objections may be raised to comparing the basic observations that were made with naturally acquired and induced malaria, since the latter is usually produced in parietic patients by the direct inoculation of infected blood from patient to patient. These objections have been met in many laboratories by using infected mosquitoes to induce the disease.

In a typical case of tertian or quartan malaria, the basic clinical symptoms of rigor, heat and sweating during a certain time of the periodic cycle are associated with the cyclical development of the parasites in the blood. The beginning and duration of the paroxysm are correlated with the rupture of the parasitized red cells and the setting free of the new crop of merozoites into the

plasma. The original observations of the associated phenomena were made by Golgi,⁴⁶ but the periodic phenomena for *P. malariae* have now been worked out in greater detail.⁴⁷ The growth of trophozoites took 54.2 hours, young schizonts 10.4 hours, and segmenters 7.4 hours, six of which were required for segmentation. The progress of segmentation was closely followed by a rise in temperature until the process was completed. A different time schedule exists in tertian and malignant tertian malaria, but the relation of the shorter paroxysm to the segmentation of the parasites is apparently the same.

The underlying phenomena causing the paroxysm are not understood. Many theories have been offered, but few facts are known. The release of the merozoites and the pigment and constituents of the ruptured red cells provides a sudden increase in protein that may cause the phenomenon. The latter is believed to be similar in some respects to an anaphylactic reaction.⁴⁸ Even though one reads in the literature about toxic substances and the increased toxicity of epidemic malaria, no concrete evidence is as yet available for the secretion and liberation of such toxic substances. Other authors⁴⁹ believe that the rise in the plasma potassium level may be responsible for the sequence of events. Beeson and Hoagland⁵⁰ found that intravenous injections of calcium chloride (10 cc. of a 10 per cent solution) stopped the rigor almost immediately.

Recent studies with the pigment (hematin) of *P. knowlesi* have identified this substance spectroscopically as ferrihemic acid.^{61, 62} The same workers tried to demonstrate the role of the pigment in the production of the paroxysm⁶³ and the lesions.⁶⁴ No evidence of a causal relation between pigment and toxicity was obtained. Toxic symptoms developed only when the reticuloendothelial system was overwhelmed by the accumulation of parasites. Furthermore, the pigment at the time of liberation from the ruptured cell was found to be insoluble in the plasma.

The observations just cited leave the cause of the paroxysm still undiscovered. In fact, the mechanisms involved in the production of the paroxysm and symptoms are still more baffling when one considers the symptomless carrier, and when one compares the numbers of parasites per cubic millimeter of blood at the onset of symptoms and for varying intervals after spontaneous cure. Usually the parasites are present in much greater numbers at the time the symptoms disappear. This phenomenon and also the relapse are no doubt related to the immune response as well as to the inherent pathogenesis of the disease.

The pathogenicity of human plasmodia differs between species and between strains of the same species. Primarily, the parasites gain entrance into the blood stream after a variable incubation period and invade the red corpuscles, where they multiply asexually and also differentiate into gametocytes. The destruction of red cells on the completion of each new asexual cycle leads to anemia, which is correlated in intensity with the severity and duration of the disease. The cellular detritus, pigment, merozoites that fail to penetrate new cells and old gametocytes are taken up by phagocytes. Since the volume of material for phagocytosis varies with the intensity of the infection, the quantity is great enough in most cases to cause a proliferation of the reticuloendothelial system. For this reason, the parasites localize in the spleen, liver and bone marrow to produce hypertrophy, hyperplasia and pigmentation.

In malignant tertian malaria, the parasitized red cells may localize in any organ because of their tendency to agglutinate spontaneously and to adhere to the walls of the small capillaries. Thrombi are then formed, leading to stasis of the blood supply and occlusion of the capillaries. Cannon⁵⁵ in an outstanding discussion of the pathology of human malaria presents a case to confirm the spontaneous agglutination of parasitized red cells. Knisely et al.⁵⁶ have demonstrated the phenomenon in vivo, using a color moving-picture film to record the sequence of events in the blood of a rhesus monkey injected with *P. knowlesi*. Rigdon⁵⁷ failed to find evidence of spontaneous agglutination in a patient dying of uncomplicated malignant tertian malaria and autopsied three hours after death. This author suggested that shock resulting from anoxemia is worth considering as the cause of death in infection with *P. falciparum*. In any case, the blocking of capillaries by parasitized red cells helps to explain the great variety of symptoms in pernicious malaria, and the sequence of events is responsible for the types known as "cerebral" and "algid." Cannon presents excellent evidence for the similarity between the courses of malarial and of bacterial infection, a fact that is not generally recognized by malarialogists.

The parasites of tertian and quartan malaria are not so invasive as is *P. falciparum*, and the counts per cubic millimeter do not approach the 300,000 to 500,000 seen occasionally in fulminating cases of pernicious malaria. The density of *P. vivax* is seldom greater than 100,000, and *P. malariae* seldom exceeds a density of 20,000. Even though the parasitic densities in quartan infection are extremely low, the paroxysms are usually very severe.

Valuable information concerning malaria in drug addicts has been obtained by clinical and

laboratory studies. The method of infection depends on the direct transmission of the parasites by the use of common hypodermic syringes. Biggam⁵⁸ first reported this type of infection among drug addicts in Cairo, Egypt, in 1929, and the first report in this country was made in 1932.⁵⁹ Additional papers from other workers in this and other countries followed within a short time. Helpert⁶⁰ presented a study of 49 cases in New York City, 29 of which were fatal. Most⁶¹ has studied over 200 cases, all except 2 of which were malignant tertian malaria. These papers deserve attention, particularly by physicians on the staffs of large city hospitals, who are more likely than others to be confronted with this type of patient. A high percentage of cases are brought into hospitals in a comatose condition because of cerebral involvement with *P. falciparum*. Early diagnosis by the demonstration of malaria parasites in the blood is necessary, this to be followed by prompt and intensive treatment in order to prevent fatalities, which even then are very high.

Most pointed out that the malignant tertian malaria seen in his series of cases differed in no way from naturally acquired infections in the tropics. Cerebral syndromes were the most frequent, but gastrointestinal or algid types were seen, along with 2 cases of hemoglobinuria or blackwater fever, 1 of which was fatal.

The course of the disease and its pathology, as studied by Helpert and by Most, were characteristic of malignant tertian malaria. Death in the majority of cases was attributed to the overwhelming infection and diffuse cerebral involvement. No observations were included that add to those made by Cannon⁵⁵ on the intravascular agglutination of parasitized cells, although photographs were shown to demonstrate the filling and occlusion of small capillaries.

PHYSIOLOGY

The physiologic pathology of malaria has been reviewed by Melency,⁶² who concludes a summary of this extensive subject by saying, "There are few infectious diseases of man which, in their severe manifestations, produce functional changes in more regions and systems of the body than malaria." Consequently, the variety of clinical symptoms caused by malaria are more understandable when the physiologic changes taking place in this infection are realized.

Of interest are recent studies⁶³⁻⁶⁵ on induced malaria made in an effort to find the cause for the edema commonly seen in parietic patients undergoing treatment. These observations demonstrated a reduction of the plasma proteins, especially that of albumin⁶³ and have led Kopp and

Solomon⁶⁴ to the conclusion that the edema is the result of reduced osmotic pressure caused by a marked fall of the albumin fraction to levels of 3 gm. per 100 cc. or below. The most important factor in determining this drop in the synthesis of albumin is the interference with its production in the liver. The destruction of red cells by the parasites accounts in part for the increase of globulin. A period of twenty-four days was required after the termination of the attack before the blood proteins returned to their normal values.

The physiology of the malarial parasites is not clearly understood because of the same difficulties that have hampered studies on humoral immunity. No adequate methods of cultivating these parasites are known, and they generally occur in a relatively low concentration in the peripheral blood during the human disease. The discovery of the simian parasite *P. knowlesi*,²⁰ which produces over 50 per cent infected red cells in the rhesus monkey, has provided a rich source of organisms for studies of metabolism and immunity. With improved methods devised during these studies, species causing less intense infections are also being investigated.

Dextrose was found to be essential for the limited survival of human plasmodia according to the technic of Bass and Johns.⁶⁶ Christophers and Fulton⁶⁷ and Fulton⁶⁸ showed that glucose causes an increase of oxygen consumption by *P. knowlesi*. Coggeshall⁶⁹ showed that *P. knowlesi* consumes six times as much oxygen as does *P. inui*. Maier and Coggeshall,⁷⁰ improving the methods of Christophers and Fulton, found that the oxygen uptake is proportional to the size or developmental stage of the organism, and that glucose appears to meet the normal energy requirements of the parasite. Application of the studies on respiration was made by Fulton and Christophers⁷¹ in order to test the effect of quinine and atabrine on the parasite in vitro. Coggeshall and Maier⁷² went one step farther and investigated the possibility of assaying antimalarial drugs by their effects on respiration and comparing the results with their therapeutic action. The in vitro method could not be used to furnish a reliable chemotherapeutic index, but had value as a supplementary test along with in vivo experiments.

The precise role of diet in racial and individual susceptibility to human malaria is not understood. The great influence that famine exerts on the intensity of epidemic malaria in India has long been noted.⁷³ However, the epidemics usually followed a period of famine, indicating that lack of proper food was a predisposing cause. Passmore and Sommerville⁷⁴ have pointed out that the association of malnutrition and malaria does not

prove that malnutrition is an essential factor in the causation of epidemics. In fact, these authors reviewed the conflicting views of various authors and in particular those of Sinton⁷⁵ who has pointed out that malaria may be the direct cause of poverty and an insufficient diet. The numerous factors involved in the general picture of adverse economic conditions are difficult to study and assess in the field.

Avitaminosis and its general effect on resistance to infection may play a part in making a community highly susceptible to an outbreak of epidemic malaria, but experimental evidence is lacking. The degree of immunity existent in the population is also a factor, because low transmission at a time of drought allows the immunity to fall to a low level in the older age groups, and is not sufficient to produce immunity in young children if they are not exposed to infection. Consequently, the complexity of factors involved in endemic and epidemic malaria has prevented accurate analyses of the part played by malnutrition and dietary deficiencies. The coincident and repeated conduct of a thorough nutrition survey in conjunction with the malaria survey in a highly malarious area over a period of years would provide invaluable medical and public-health data.

Clinical investigations by Lotze⁷⁶ showed that greater quantities of vitamin C than normal were utilized by patients with benign tertian malaria, and the vitamin was found to play a part in salt and iron metabolism. Mohr⁷⁷ confirmed these findings and insisted that no causal relation exists between malaria and avitaminosis C; the administration of additional vitamin C, he stated, aids convalescence from malarial anemia by enhancing the value of iron.

Passmore and Sommerville,⁷¹ working with simian malaria and diets deficient in vitamins A and C and calcium, failed to demonstrate differences in primary infections between a well-nourished and a poorly nourished group of monkeys. Actually, the average parasite counts were higher in the well-nourished group. This finding at least confirms the observation that a good state of nutrition does not reduce the severity of primary attacks of malaria in human beings.

The relation of biotin to susceptibility to avian malaria has recently been studied by Trager.⁷⁸ When ducks and chickens on a deficient biotin diet were injected with *P. lophurae*, 50 to 100 per cent heavier infections developed. The parasite count remained high several days longer and the mortality was greater than among the controls. At the peak of the malarial infection, the concentration of biotin in the blood reached two to three times its normal value, a fact that Trager points

out may well be concerned with the elimination of the parasites from the blood stream. The application of these results to similar studies on human and simian malaria should provide some interesting and highly valuable data.

CASE 29321

PRESENTATION OF CASE

A fifty-one-year-old unmarried woman, a stenographer, entered the hospital because of "generalized weakness."

Approximately one month prior to admission the patient noticed increasing difficulty in climbing stairs because of "weakness in the knees." Two weeks before admission her ankles began to swell, particularly in the evening, and at times her face was slightly swollen. Weakness gradually became generalized, and she felt extremely fatigued each evening. Her physician noticed that her voice had become quite deep, acne had developed on the face, hair had grown on her upper lip and chin, and her eyebrows had become bushy. She had gained 3 pounds in the previous month. During the two years prior to admission she had occasionally suffered with bitemporal headaches, often associated with palpitation. There had been no dyspnea, cyanosis or angina.

The family history was noncontributory. Twenty-six years prior to admission, a panhysterectomy, right oophorectomy and partial left oophorectomy were done for ovarian cysts and endometriosis. Menses ceased after this operation but no hot flashes occurred.

Physical examination revealed a large woman, weighing 175 pounds, who talked in a rather husky tone. The eyebrows were bushy. Hair was prominent on the upper lip and to a less extent on the chin. The hair on the head was not remarkable. The fundi were normal. There were crusted and pustular lesions on the face and between the breasts. The cheeks were fat. The subcutaneous fat seemed abundant on the trunk, upper arms and thighs. The skin was rather flushed; several small striae were present over the iliac crests. Both breasts were small. The heart, lungs and abdomen were normal. Vision was 20/20 in the right eye and 20/25 in the left eye. The visual fields and blind spots were normal. There were many fine and deep varicosities of the legs and thighs. Pelvic

examination revealed an absence of organs or masses. One examiner believed the clitoris was slightly enlarged. The tendon reflexes were sluggish. Muscular weakness was generalized but more evident in the lower extremities. No muscular twitches were noted, and there was no muscle tenderness. Sensations to pinprick and light touch were normal. The position and vibration senses were reduced in the legs, but the plantar reflexes were normal.

The blood pressure was 220 systolic, 106 diastolic. The temperature was 99.2°F., the pulse 84, and the respirations 20.

Examination of the blood revealed a red-cell count of 4,860,000 and a white-cell count of 10,300, with 89 per cent neutrophils. The urine was alkaline and had a specific gravity of 1.012; the sediment contained 2 white cells per high-power field and a great deal of amorphous material, and the urine gave a "green with slight precipitate" test for sugar. A blood Hinton test was negative. The fasting blood sugar was 127 mg. per 100 cc., and the nonprotein nitrogen 20 mg. The chloride was 92.0 milliequiv. per liter. The prothrombin time was 23 seconds (normal, 19 seconds). The total protein was 4.8 gm., the albumin 3.1 mg., the globulin 1.7 mg., the calcium 9.6 mg., and the phosphorus 3.1 mg. per 100 cc. Another fasting blood sugar before a glucose tolerance test was 156 mg. per 100 cc., and the test levels were 262 mg., 282 mg., 300 mg. and 360 mg. in one half, one, two and three hours respectively. There was no sugar in the urine specimens collected during the test. A phenolsulfonephthalein test showed 45 per cent excretion, 15 per cent in the first fifteen minutes. The fasting blood sugar before an insulin tolerance test was 136 mg. per 100 cc.; the test levels were 115 mg., 94 mg., 85 mg., 91 mg., 111 mg. and 123 mg. at twenty, thirty, forty-five, sixty, ninety and one hundred and twenty minutes after the intravenous injection of 7.9 units of insulin. Adrenalin (0.79 cc. of a 1:1000 solution) was then administered, and forty-five and sixty minutes later the blood sugar levels were 162 mg. and 145 mg. per 100 cc. respectively. In three examinations the 17-ketosteroids were 16.8 mg., 10.4 mg. and 10.2 mg. in twenty-four-hour urine specimens. The urine contained less than 6.6 mouse units of follicle-stimulating hormone per twenty-four-hour urine specimen. The basal metabolic rate was +15, +7 and -1 per cent in three satisfactory determinations.

An electrocardiogram revealed a normal sinus rhythm of 70. The PR interval was 0.14 second. There was high voltage in the standard leads. The QRS complex was 0.09 to 0.10 second. Q₁ was 11 mm., and Q₄ 1 mm. There was evidence of

*On leave of absence.

moderate left-axis deviation. T₁ was upright, and T₂ inverted. There was slight sagging of the ST segment in Lead 2. The T wave was inverted in Lead 3, and there was late inversion of the T wave in Lead 4. The spinal fluid was normal.

A chest roentgenogram was negative except for a linear scar in the left lower lung field. The heart was transverse in position, and the aorta tortuous. X-ray examination of the skull showed a normal sella turcica. There was considerable increased density along the suture between the squamous portion of the temporal bone and the parietal bone. The squamous portion of the temporal bone was thin. A lateral view of the thoracic spine showed moderate osteoporosis. There was no evidence of vertebral fracture. The kidneys appeared normal in size, shape and position. There was an irregular area of calcification low in the pelvis. Intravenously injected dye appeared promptly in both kidneys. There was incomplete visualization of the calyces and pelves owing to overlying bowel content. The ureters appeared normal. The area of calcification was partially obscured by the bladder shadow. A barium enema was negative except for several diverticula in the sigmoid. There was no definite evidence of extrinsic pressure on the bowel.

The patient was treated symptomatically and discharged unimproved on the twenty-third hospital day. Her diabetes was controlled by diet without insulin. On the day of discharge the chloride was 78.5 milliequiv. per liter, and the nonprotein nitrogen 23 mg. and the sugar 162 mg. per 100 cc.

Final admission (five weeks later). The patient re-entered the hospital because of increased generalized muscular weakness and dryness of the mouth.

The patient looked apathetic, but seemed quite comfortable. Scattered fine and medium moist rales were audible at the lung bases posteriorly. The heart and abdomen were normal. There was slight pitting edema at the sacrum and increased weakness of the hands and back. The muscles of the hands, calves and thighs were atrophied, but no fibrillations were seen. The tendon reflexes were sluggish, although there was marked reduction in vibration sense and in two-point discrimination in the lower extremities. Pinprick was felt less acutely on the legs than on the trunk and upper extremities, although the soles of the feet were very sensitive. Perception of light touch seemed normal.

The blood pressure was 135 systolic, 90 diastolic. The temperature, pulse and respirations were normal.

The red-cell count was 3,850,000, and the white-cell count 9600, with 93 per cent neutrophils. The urine was neutral in reaction, had a specific gravity of 1.015 and gave a ++ test for albumin and an olive-green test for sugar. The sediment contained 25 white cells per high-power field and a great deal of amorphous debris. The creatine and the creatinine urinary excretions were 360 mg. and 512 mg., respectively, in twenty-four hours. The blood nonprotein nitrogen was 28 mg. per 100 cc. and the sugar 244 mg.; the carbon dioxide combining power was 37.3 millimols per liter. The vital capacity was 30 per cent of normal. In a flat plate of the abdomen the left kidney was lower than usual. There was a shadow somewhat suggestive of a mass above the kidney, but this was not definite.

A biopsy of a leg muscle was done. The surgeon commented on the difficulty in finding any muscle tissue. The sections showed degenerative changes in the muscle fibers, as evidenced by a marked increase in sarcolemma nuclei. There was some increase in fat and connective tissue.

The blood sugar remained high despite 20 units of regular insulin and 20 to 30 units of protamine zinc insulin daily, but the urine was freed from sugar by the insulin. Two weeks after admission the carbon dioxide combining power was 34.4 millimols, the chloride 84.5 milliequiv. and the sodium 140.8 milliequiv. per liter. The protein was 3.8 gm., the albumin 2.4 gm. and the globulin 1.4 gm. per 100 cc. The pH of the blood was 7.39. The urine at that time was alkaline and gave a + test for albumin; it showed a ++++ test for chloride in the twenty-four-hour specimen. The sediment contained 6 white cells per high-power field, amorphous debris and many bacteria.

The patient was treated with testosterone propionate. Since the urinary output was 940 cc. per day, ammonium chloride was administered, producing a marked diuresis. Approximately one month after admission petechial hemorrhages were noted in the skin of the abdomen, particularly in an abdominal scar, and of the chest. The prothrombin time was 28 seconds (normal, 20 seconds). The sugar was 235 mg., the protein 4.2 gm., the calcium 8.7 mg., and the phosphorus 13 mg. per 100 cc. The carbon dioxide combining power was 35.1 millimols per liter; the chloride was 83.9 milliequiv., the potassium 3.18 milliequiv. and the sodium 133.9 milliequiv. per liter. The pH of the blood was 7.7. The total 17-ketosteroid excretion was 11.8 mg. every twenty-four hours (alpha type 8.4 mg., and beta type 3.4 mg.). The urine was negative for 3 mouse units of follicle-stimulating hormone, per twenty-four-hour speci-

men. A perirenal air injection disclosed a smooth mass, measuring 9 by 6 by 0.5 cm., overlying the superior pole of the left kidney at the level of the eleventh and twelfth ribs. There was considerable air in the fascial planes and probably within the abdomen. Twenty-four hours after the injection there was a large amount of mediastinal emphysema and subacute emphysema in the neck. The patient gradually became drowsy and uncooperative, and increasing edema developed in spite of the administration of Mercupurine.

On the thirty-third hospital day Cheyne-Stokes breathing developed, the blood pressure dropped in spite of transfusions and coramine, and the patient lapsed into coma and died.

DIFFERENTIAL DIAGNOSIS

DR. MAURICE FREMONT-SMITH: This fifty-one-year-old stenographer complained of generalized weakness and swelling of the ankles for a month before admission. She had acne of the face, and hair on the lips and chin; the eyebrows had become bushy, and her voice deep.

I think the best way to discuss this case is to "jump in" on the question of Cushing's disease, because the symptoms of weakness, slight masculinization, hirsutism, high blood pressure and diabetes, make a discussion of this disease inevitable.

Cushing's syndrome is usually, if not always, associated with hyperplasia or cancer of the cortical cells of the adrenal gland and frequently with certain changes in the basophilic cells of the pituitary gland. Cushing found basophilic adenomas in many of his cases, but such adenomas have not always been found in this syndrome,* and their significance is still not clear.

One thinks of the adrenal gland as the primary etiologic factor in Cushing's syndrome, and there are a number of factors here that favor this syndrome. I should mention particularly two things: the type of the diabetes, and the very low amount of follicle-stimulating hormone in the urine. A low excretion of follicle-stimulating hormone can be present with destruction of the pituitary gland (as in panhypopituitarism) and also following suppression of pituitary activity by estrin producing tumors (arrhenoblastomas). We must remember the possibility of the latter in this case, because although most of her pelvic organs were removed at an earlier age for endometriosis, part of one ovary was left and arrhenoblastoma was therefore still possible.

The type of diabetes here, the insulin-resistant variety, is found in Cushing's syndrome. Protein

is rapidly turned into sugar; and this not only leads to too much sugar (diabetes) but to too little protein (accounting for the weakness). There is no absence of insulin in this condition; hence, the administration of insulin produces slight, if any, lowering of the blood sugar and does not make up for the defect. This patient had marked insulin resistance. In the insulin-tolerance test, in thirty minutes after the injection of a proper amount of insulin, the blood sugar should be about half the fasting level. Here the thirty-minute level was well over half the fasting level. Moreover, insulin given to this patient did not control the diabetes.

In Cushing's syndrome there is also a slight increase in the excretion of 17-ketosteroids. Such an increase was present in this case. The acne is typical. The blood pressure is characteristic. But when one comes to the further laboratory data and the subsequent course one's hope for Cushing's syndrome is greatly upset. In the first place this patient was running a constant alkalosis and had a very low serum protein. The alkalosis I think could be explained by the loss of chloride. The urine contained a large amount of chloride, and the blood chloride, even in the first examination, was extremely low. If a person is losing chloride without losing base, alkalosis will certainly result. The patient was not vomiting. Why she was not losing base, I do not know. I hope I shall get help from someone here. The low serum chloride is one of the characteristic changes that take place in Addison's disease, but in Addison's disease sodium is also lost, and potassium retained. Consequently we are faced with what looks like hyperactivity of certain cortical cells on the one hand (Cushing's syndrome) and loss of activity of the cortical cells on the other.

DR. TRACY B. MALLORY: Do you not mean medullary cells?

DR. FREMONT-SMITH: No; I mean cortical cells. As I said, some factors here suggest overactivity of the cortical cells, others underactivity. I think that can possibly be explained by the fact that in Cushing's syndrome the androgenic cells are the overactive cells.[†] In a case reported by Wilkins,¹ there was hyperplasia of the adrenal androgenic tissues and death resulted from corticoadrenal insufficiency. I wish to see whether I can fit this case into a similar type of lesion.

Let us run through the vast amount of laboratory work here. The chlorides were low, and the nonprotein nitrogen was normal, which is against Addison's disease. The low total protein probably accounted for the edema. Low total protein is

*The term "Cushing's syndrome" is used when speaking of the clinical picture without regard to the etiology. The term "Cushing's disease" is reserved for those cases with basophilic adenoma of the pituitary gland.

[†]This is a misstatement. M F 5

not found in Addison's disease because the body loses water, together with the electrolytes, and hemoconcentration results. The calcium was 9.6 mg., and the phosphorus 3.1 mg. I should not make any reference to the calcium, even in the presence of the low serum protein, if it were not for the fact that later on, when the calcium was lower (8.7 mg.), the phosphorus was 1.3 mg. That is probably a red herring, but if you will remember that in determining the serum calcium you must add 1 mg. to the calcium reading for every milligram the total protein falls below 7 mg., you will see here that by adding 3 mg. to the calcium value one is left with a figure of 11 mg.; this and a phosphorus level of 1.3 mg. are consistent with hyperparathyroidism. I only raise that as an interesting speculation and will ask Dr. Albright to say a word about it. The renal function was somewhat low, — 15 per cent in the first fifteen minutes, — but it does not seem that the kidney function was badly damaged.

The ketosteroids were high for a woman who is as sick as this woman was. Normally the alpha type represents 90 to 95 per cent of the total ketosteroids. I am tempted to make a diagnosis of cancer of the adrenal cortex on the basis of the high percentage of beta ketosteroids reported here. But in all the cases of adrenal cancer about which I have heard the total excretion of ketosteroids is extremely high, ranging from 50 to 100 mg. in twenty-four hours. In my diagnosis I shall be influenced more by the comparatively low ketosteroid excretion than by the disproportion of the alpha and beta steroids. I shall therefore make a diagnosis of hyperplasia rather than cancer of certain cells of the adrenal cortex, with consequent pressure on the cortical cells that secrete the anti-Addison's disease hormones. I may be absolutely wrong, but I make it on the basis of the absence of a great increase in excretion of total ketosteroids.

Running through the other facts here, I think the electrocardiogram shows coronary heart disease, but not coronary thrombosis. This, again, is consistent with Cushing's syndrome, which is often accompanied by coronary disease. The absence of x-ray evidence of tuberculosis in the chest makes Addison's disease unlikely, since about 80 per cent of Addison's disease is the result of tuberculosis. There was not, as there often is in Cushing's syndrome, a high red-cell count. I should also mention the creatine output, which was extremely high in this case. The normal woman puts out little creatine, and this large output is consistent with Addison's disease, as well as with hyperthyroidism and myasthenia gravis. The creatinine output was low, which is consistent with the paucity of muscle tissue ob-

served by the surgeon. The biopsy of the leg muscle I shall not discuss.

The only other important thing is the finding by perirenal air injection of a tumor above the left kidney. May we see the x-ray films?

DR. LAURENCE ROBBINS: This skull film shows a sella that is normal in size and shape with perhaps slight decalcification of the vault. The bones of the spine are decalcified, and in this film we are able to see that the left kidney is considerably low in position and that there is a suggestion of a mass above it. Although these films were taken after an air injection, unfortunately the air did not choose the right pathway to help us out. It failed to outline the kidney and adrenal gland as well as it often does, but there is a mass lying in this area above the kidney that is outlined by the air in part, and I can say that, in spite of the normal upper pole of the kidney, which can be seen in the lateral view, there is something lying above it. This chest film was taken rather late in the disease and simply shows atelectasis and the decalcification of the bones, which have been seen elsewhere. I do not see anything to suggest active tuberculosis. Possibly some of these areas of density represent old areas of calcification.

DR. FREMONT-SMITH: I have not explained the low serum protein, except possibly by inanition. I shall make a diagnosis of hyperplasia of certain groups of cells of the adrenal cortex, with pressure on the other parts of the cortex and resultant destruction and Addison's disease; and in the pituitary gland I expect to see nothing except the changes in the Crooke cells that may go with Cushing's syndrome. There may be hyperplasia of the parathyroid glands. I believe there will be no lesion in the pancreas or ovary. There will also be the changes that go with hypertension; some arteriosclerosis, coronary heart disease and sclerosis of the kidneys.

DR. FULLER ALBRIGHT: I am afraid that I have been guilty of spreading misinformation. We did at one time think that all cases of cancer of the adrenal gland had a very high 17-ketosteroid excretion. This was true of our first 3 cases; however, some of our other cases had normal or only slightly elevated values. They had a case of cancer of the adrenal gland with Cushing's syndrome and normal ketosteroid excretion at the Mount Sinai Hospital in New York City. Concerning beta ketosteroids, when they are high it probably means cancer; when they are low, however, it does not mean that it is not cancer. Their excretion was not high in this case, in spite of the fact that, as Dr. Fremont-Smith has stated, their percentile

value with regard to total 17-ketosteroid excretion was increased.

The low serum phosphorus was probably the result of giving testosterone. When testosterone is administered, new tissue is formed and that takes a lot of phosphorus.

There are so many things to talk about that it is difficult to choose the significant points.

A PHYSICIAN: Did the patient have edema?

DR ALBRIGHT: Yes; marked edema.

Let us talk about electrolytes. If she had Cushing's syndrome, presumably she had too much of some adrenocortical hormone. So in the electrolytes one might expect the opposite picture of that seen in Addison's disease. In Addison's disease, there is a low sodium, a low chloride, a normal carbon dioxide combining power and a high potassium. This patient had a normal sodium, a low chloride, a high carbon dioxide combining power and a low potassium. In other words, the findings were not typical of those observed in Addison's disease, with the exception of the chloride. Dr. Fremont-Smith says that she was losing chloride through the urine without base. The urine was alkaline so there was base of some kind with the chloride. It is clear that the high carbon dioxide combining power was compensatory to the low chloride, but otherwise I cannot put the electrolyte picture together. Dr. Edwin Kepler² of the Mayo Clinic has had 3 patients with Cushing's syndrome who had exactly the same alterations in their blood electrolytes. In these cases there was the same tendency to hemorrhage that this patient showed hemorrhage into the subcutaneous tissue. Dr. Kepler's cases all showed hyperplasia of the adrenal glands.

DR FREMONT-SMITH: What was the argument for treating with testosterone?

DR ALBRIGHT: We know that in Cushing's syndrome the patient is suffering from lack of tissue—no muscle, no bony matrix, thin skin and so forth. Testosterone is the hormone par excellence that makes everything grow. This is a type of symptomatic treatment that works well in certain cases. I think Dr. Fremont-Smith's conclusions that this patient was suffering from overfunction of certain functions of the adrenal glands and underfunction of others come very close to explaining the facts.

CLINICAL DIAGNOSES

Cushing's syndrome
Carcinoma of adrenal cortex

DR. FREMONT-SMITH'S DIAGNOSES

Hyperplasia of the adrenocortical cells.
Addison's disease?
Hypertensive heart disease.

ANATOMICAL DIAGNOSES

Adenocarcinoma of left adrenal gland, with metastases to the liver, lung and bronchial lymph nodes

Atrophy of right adrenal gland.

Central necrosis of liver.

Pulmonary edema, moderate.

Hydrothorax, bilateral.

Cardiac hypertrophy, hypertensive type

Peripheral edema, moderate.

Hirsutism.

Atrophy of skin and muscles

Operation perirenal air injection, left.

Mediastinal emphysema.

PATHOLOGICAL DISCUSSION

DR MALLORY: The post-mortem examination answers some of the questions, but many others are unanswered.

The primary finding was a large tumor, weighing 180 gm., in the left adrenal gland. This was cortical in type. It was a malignant tumor and had caused a large metastasis to the right lobe of the liver and also small metastases in the lungs and bronchial lymph nodes. One of the interesting findings was the size of the right adrenal gland, which showed extreme atrophy, weighing only 1.6 gm. One adrenal gland was completely replaced by tumor, and the other extremely atrophic. I think that that probably explains fairly well this queer combination of evidence of hyperactivity and subactivity of the adrenal cortex at the same time.

We were limited by the autopsy permission to an abdominal incision, so I cannot tell you about the parathyroid or pituitary glands. We were unable to find any recognizable trace of ovary. There certainly could not have been any ovarian tumor. The heart showed moderate hypertrophy and slight coronary disease. The lungs showed a moderate amount of emphysema. The one other finding that may have been influenced by some of the metabolic conditions was a rather severe extensive central necrosis of the liver. It is not possible to say how long it had existed. I think it was probably a matter of only a few days before death, but perhaps the final hemorrhages can be explained that way. I doubt if it was of long enough duration to have caused the consistently low serum protein.

DR ALBRIGHT: How about the muscles?

DR MALLORY: They were extremely atrophic.

DR ALBRIGHT: No scar tissue?

DR MALLORY: No.

DR FREMONT-SMITH: Do you think the air injection was the cause of death?

DR. MALLORY: I do not believe so. Several days had intervened. There was detectable emphysema in the mediastinum at the time of autopsy, but that had nothing to do with the patient's death.

DR. ALBRIGHT: How about the smooth muscle in the adrenal glands?

DR. MALLORY: I looked at that with interest but could not make out anything wrong with it.

CASE 29322

PRESENTATION OF CASE

First admission. A twenty-seven-year-old woman entered the hospital complaining of chest pain.

The patient had felt perfectly well until one and a half years before admission, when suddenly a severe pain developed in the chest immediately to the left of the sternum at the level of the third interspace. It was an aching pain that occasionally radiated to the left neck and was aggravated by deep breathing, sneezing and coughing. At night it was severest, and frequently awakened the patient. The attack lasted only two or three days, but during the ensuing months there was an occasional mild ache in the same location.

One evening five months before admission the severe pain returned, and in the morning, numbness had developed in the left chest and arm and the patient found that she was unable to move the trunk, left arm or head. Her physician could detect nothing abnormal on physical examination, but suggested an x-ray film of the chest; this advice was not followed. Within the next few days the pain and numbness dwindled, and at the end of a week the patient returned to her work as a stenographer. During the next three weeks a dry cough came and went, and in the fourth week the pain disappeared completely. Three months later the symptoms recurred, and the patient began to suffer from anorexia, nervousness and fatigue, and weight loss became perceptible. Again the pain disappeared within a few days, but returned in its severest form one month before admission. Its characteristics were always the same, but in addition it was aggravated by lying on the left side and was eased somewhat by resting on the opposite side. Three weeks before admission a chest plate taken at an outside institution showed a definite abnormality in the left chest. A week later the patient contracted a sore throat

and head cold, accompanied by dull pain in the left side of the chest. She went to bed. Her temperature was normal each morning but rose to 99.2°F. each afternoon. During the next few weeks a dry cough developed but discomfort was experienced only on deep breathing. At no time had there been hoarseness, sputum, hemoptysis or night sweats. A loss of 12 pounds had occurred in the previous four months.

At the age of two the patient had suffered from influenza complicated by pneumonia. In the next year a swelling developed in the left side of the neck; this finally ruptured and drained. Her tonsils and adenoids had been removed when she was seven years old. In general the patient contracted three colds a year, which usually were accompanied by a sore throat and lasted two or three weeks. Her father had died of rheumatic heart disease at the age of twenty-six.

On examination the patient was well developed and somewhat emaciated but in no apparent distress. An 8-cm. vertical scar was present on the left side of the neck, starting just below the ear. The tonsils and uvula were absent. The chest was symmetrical, with a questionable lag on the left. At the level of the second and third ribs on the left side and extending from the midline laterally for 6 cm. there were slight percussion dullness, increased tactile fremitus and slightly decreased breath sounds. The dullness blended with the cardiac area below. There was some doubt about these abnormalities for they could not be detected by other examiners with any consistency. Examination of the heart, abdomen and nervous system was normal.

The blood pressure was 120 systolic, 74 diastolic. The temperature swung between 98 and 100.5°F., the pulse averaged 90, and the respirations were normal.

Examination of the urine was negative. The blood showed a red-cell count of 4,500,000, with a hemoglobin of 13.5 gm., and a white-cell count varying between 7000 and 14,000, with 75 per cent neutrophils. The blood Hinton test and examination of the stools were negative. No tubercle bacilli could be found in the gastric washings. The tuberculin test in a dilution of 1:10,000 was negative, but in a dilution of 1:1000 there was a 2-cm. area of erythema in thirty-six hours that increased to 3 cm. in forty-eight hours, with a 2-cm. ring of induration.

X-ray films of the chest showed a 6-by-5-cm. oval mass with flamelike excrescences at the left hilus, and a lateral film placed it in front of the hilus. The hilar shadows themselves seemed normal in size, shape and position, and the lungs were otherwise clear. The chest films taken three weeks

before in another institution were said to have shown a fairly smooth-bordered triangular mass, 5 cm. wide, extending out from the left hilus. An intravenous pyelogram revealed nothing abnormal.

During hospitalization the patient received 1800 r of x-ray therapy front and back, directed

DIFFERENTIAL DIAGNOSIS

DR. HELEN PITTMAN: Have we the x-ray films?

DR. MILFORD SCHULZ: This is the film (Fig. 1) taken at the first admission. It is somewhat overexposed but shows the triangular area of density arising in the left hilus. The ribs are intact

FIGURE 1. Roentgenogram of Chest.

toward the left hilus, over a seven day period. Two days later she was discharged to the Out Patient Department.

Second admission (three weeks later). In the interval the patient remained in bed except for visits to the Out Patient Department. Her temperature had varied between 99.6 and 101.0°F., and she was always aware of pain, although it was not sharp unless she took a deep breath, sneezed, lay on the left side or sat straight up.

A chest film taken two weeks after completion of the x-ray therapy showed that the lesion had not responded; indeed, the examiner believed it to be somewhat larger.

On the tenth hospital day an operation was performed.

and there is no fluid in the chest. The next film was taken after she had received 1800 r, and the lesion, if anything, is larger than in the one taken before radiation. In the lateral film the lesion is at the base of the upper lobe and extends almost to the anterior chest wall.

DR. PITTMAN: Do you think it arises in the mediastinum?

DR. SCHULZ: No; I think it arises in the hilus.

DR. PITTMAN: From the record alone, before seeing the x-ray films, I thought that the lesion was mediastinal. I shall have to change my ideas.

This is a story of sudden onset followed by acute attacks with remissions of one and a half year's duration in a twenty-seven-year-old woman. There is a definitely positive tuberculin test, which

I am inclined to accept as a fact but not to relate to the present lesion. I think that a positive tuberculin test in a dilution of 1:1000 in a twenty-seven-year-old person occurs often enough so that we cannot put too much faith in its having anything to do with this lesion.

Going back to the childhood of this patient, the influenza, the pneumonia and the swelling in the neck are closed episodes. I do not believe they had anything to do with the present illness.

There are queer neurologic findings. Five months before admission the pain in the chest returned with numbness of the left chest and arms and the patient was unable to move the trunk, left arm or leg. This was probably not due to neurologic disease. I think she had pain and was unable to use them for that reason. There is no other evidence suggesting involvement of the nervous system.

Then we come to the time of admission, when the patient was running a low-grade fever, with slight leukocytosis, a positive tuberculin test, chest pain, and very questionable physical findings, which I think are reasonably consistent with the x-ray films. At no time did she have hoarseness, sputum or hemoptysis. She had lost 12 pounds in the previous four months, and it is stated that more than a year ago the patient began to lose her appetite. Whether she lost her appetite from this process, whether it was enough of a process to make her lose weight or whether she lost weight merely because she lost her appetite, I cannot say.

What are the things that could cause a lesion of this sort in the chest? We think of infections, and of course we think first of tuberculosis. I am disregarding tuberculosis as being of probable importance here. She had signs that are consistent with an infection, but I think it was secondary to the process in the lung—whatever it is. The first time she noticed any fever was shortly before she came into the hospital, when it went to 99°F., and in the hospital it rose to 100.5, which is not convincing. She had a leukocytosis, which is consistent with infection. The fact that the pain came and went is not helpful, because what evidence we have does not show that the lesion became larger, and it does not appear to be the kind of lesion in which recurrent episodes of bleeding cause pain from pressure.

Finally we come to new growth, which deserves serious consideration. It is quite obvious that that is what they were looking for when the patient was on the ward. They were thinking of metastasis from a hypernephroma, I assume, when they did a pyelogram. Then the question of lymphoma

probably arose. She was, however, given much more than a lymphoma dose of radiation. Eighteen hundred roentgens is more than enough to knock out a lymphoma or any of that group, although Dr. Holmes told me yesterday that there have been one or two lymphosarcomas that have remained unchanged with that degree of radiation.

If this was in the lung root, which I believe it was, we have to think seriously of carcinoma. I can recall only one case of primary bronchiogenic carcinoma in which the bronchus was so completely occluded that there was at no time any sputum or bleeding. That was in a patient whose first symptoms were those of a mediastinal syndrome from pressure, but that is certainly extremely rare. The lesion is a little too far out to have been a dermoid cyst, which was my diagnosis when I came in. I shall drop that idea and say that it was a new growth that was infiltrating outward, was increasing in size and had survived 1800 r without shrinkage. Therefore, despite the fact that at no time had there been sputum or bleeding, I think that the most reasonable diagnosis, in view of these films, is bronchiogenic carcinoma.

DR. WILLIAM B. BREED: Now that Dr. Pittman has committed herself, I should like to ask Dr. Schulz if he will examine these films again and explain why the original diagnosis by the X-ray Department was lymphoma.

DR. SCHULZ: I know the answer, but I did not know it when I saw these films. Undoubtedly, the flame-like appearance extending into the left lung was Dr. Schatzki's reason for raising the question of lymphoma and for suggesting that a therapeutic trial of radiation be given. These flaring extensions of infiltration into the lung substance are seen every now and then in lymphoma. When it did not respond to radiation, a malignant lesion primary in the bronchus was considered. One member of the department was rather firmly convinced that it was inflammatory.

DR. BENJAMIN CASTLEMAN: Dr. Adams, would you like to comment?

DR. RALPH ADAMS: I think that the lesion was not a carcinoma but was tuberculous in origin and that it can be classified under the general heading of tuberculoma. Tuberculoma, strictly speaking, is thought of as a circumscribed lesion without bronchial communication and without spillage of tubercle bacilli. However, there is another type of tuberculous lesion, to which it is hard to give a one-word name, that fills all the requirements of tuberculoma except that it is incompletely localized or encapsulated. In the x-ray film there seems to be some parenchymal involvement beyond the

mass itself. If I had been discussing the case I think I should have concluded with a diagnosis of tuberculoma, qualifying this term as not strictly meeting all the requirements for accurate pathological description of the lesion.

DR. BREED: I saw this patient two days after she came into the hospital. We then had the re-

as second." After that I confirmed Dr. Pittman's finding that there were crepitant rales above the heart, but I heard none toward the axilla.

DR. CASTLEMAN: Dr. Sweet, will you tell us of your operative findings?

DR. RICHARD SWEET: My first knowledge of this patient was when I wandered into the X-ray De-

FIGURE 2. Photograph of a Cross Section of the Lung.

port of the X-ray Department; also the house-officers had reported dullness above the heart extending out toward the axilla, which I was unable to find. Dr. Pittman, this is the patient whom I asked you to examine without knowing about the case, and you may remember that you found some rales above the heart.

DR. PITTMAN: I do, Dr. Breed.

DR. BREED: On April 12 I wrote as follows: "Unprejudiced by knowledge of previous x-ray findings or physical examinations, I find absolutely nothing abnormal in general and in particular with relation to the chest. X-ray interpretation: lymphoma. From the history I should be inclined to put tuberculosis as first choice, and lymphoma

partment one morning and they asked me to look at these plates, which were on the illuminator. Without knowing anything about the patient I said, "This is a carcinoma," which was a rash statement. Then I heard the story about lymphoma and the lymphoma dosage. We went into the matter further, and I said, "Whatever it is, the patient should be operated on."

There were two things—the sex and the age—against the diagnosis of carcinoma. But, even in the absence of bloody sputum, we still entertained that diagnosis. I did not believe it was a tuberculoma because it did not have the x-ray appearance of those that we have observed in this hospital. Even at operation it looked exactly like a neo-

plastic infiltration of the lung—it had a nodular puckered appearance on the surface and was adherent to some of the pericardial fat tabs. I was convinced that I was removing a carcinoma.

CLINICAL DIAGNOSIS

Carcinoma of lung.

DR. PITTMAN'S DIAGNOSIS

Bronchiogenic carcinoma.

ANATOMICAL DIAGNOSIS

Tuberculoma of lung.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The external surface of the lesion did present a dimpled, depressed, firm area with small subpleural nodules, such as are seen in carcinoma. A cross section of the lung (Fig. 2) showed a 5-by-3-cm. lesion that was pyramidal shaped and composed of numerous round foci of caseation. There was a very dense band surrounding most of the lesion but in some areas the process had spread in an irregular fashion to blend with the surrounding parenchyma. We found no communication with the large bronchi, but a

few of the small branches of the apical bronchus ran through the lesion. Microscopically, the tubercles were active and were separated from each other by broad bands of fibrous tissue. I suppose tuberculoma is the best name for a lesion of this kind, even though it was not completely encapsulated. One regional lymph node also showed caseous tuberculosis.

DR. SWEET: This case reminds me a great deal of certain conditions in the colon. Not long ago two cases with annular constricting lesions in the right colon were discussed in which the diagnosis before and at the time of operation was carcinoma. In both cases the lesion turned out to be tuberculosis. The surgeon under such circumstances is undecided whether to remove the lesion or not. Thinking that in this case the mass was a carcinoma, I went ahead and did a total pneumonectomy. She made a good recovery and went home four weeks after operation.

DR. CASTLEMAN: So far as the operation is concerned, I believe that the treatment was excellent. Although thoracic surgeons are now performing more lobectomies and pneumonectomies for tuberculosis, with good results, in the past tuberculomas were usually resected under the mistaken diagnosis of lung tumor.

MALARIA

A CONSERVATIVE estimate of men from Massachusetts who have gone into the armed forces is approximately 250,000. These men have been dispersed to camps and schools in this country and to widely scattered outside areas, ranging from Iceland and Alaska to numerous tropical countries and including the fighting fronts in Africa and the South Pacific. A sizable number of these men are now in endemic and even hyperendemic malarious localities, and a certain percentage will contract malaria. The treatment of malaria in the field and at base hospitals is seldom adequate and radical cures are difficult to obtain, leading to the

development of chronic or latent malaria, which persists for varying lengths of time. Tertian malaria (*Plasmodium vivax*) can persist for about three years, malignant tertian (estivo-autumnal) malaria (*P. falciparum*) for approximately one year, and quartan malaria (*P. malariae*) for as long as six or seven years, after which the infections apparently disappear spontaneously.¹ That these figures need revision is shown by occasional references in the literature to the persistence of quartan parasites in adults for as long as thirty years.²⁻³ A latent infection is usually detected in the recipient of a blood transfusion when the donor harbored the infection unknowingly. Thus, with the ability of malarial parasites to persist for varying lengths of time, one can expect to see malaria frequently in troops returning from this war. In World War I this problem did not develop because the troops fought mainly in nonendemic areas.

In a recent report, the Medical Department of the Pan American Airways⁴ states that 46 of 284 men in Africa experienced acute attacks of malaria in spite of the fact that they were taking prophylactic doses of quinine. In an unprotected group, 87 cases of malaria developed in 100 men within five months. Furthermore, Coggeshall⁵ writes that malaria reaches epidemic proportions in combat areas where control is difficult, and that it has been estimated that over 85 per cent of the men of each regiment at the fall of Bataan had acute malaria. Information such as this gives one an inkling of what to expect in returning troops.

Fortunately there is every evidence that the medical personnel is being well prepared and equipped to deal with malaria.⁶ Likewise, it is the duty of physicians responsible for health on the home front to become acquainted with the pertinent newer knowledge about accurate diagnosis and treatment of clinical malaria.⁷ All cases of malaria, military and civilian, should be reported to local and state health officials. If the cases occur during the summer months, and hence the breeding time for anopheline mosquitoes, persons with malaria and patients undergoing treat-

ment should sleep in adequately screened rooms to prevent transmission. Finally, the patient's blood should be examined for parasites from time to time, to be certain that a radical cure has been effected, since relapsing cases are also a source of parasites for transmission.

The QAP treatment (quinine, atabrine and plasmochin), which is the method of choice for treating acute malaria,^{8,9} will be restated in the report on medical progress beginning in this issue of the *Journal*. Few physicians outside the large cities will have access to all these drugs, but quinine or atabrine therapy should be sufficient for the majority of cases. The plasmochin has been included in the combined treatment because this drug specifically affects the gametocytes of *P. falciparum*, thus preventing the transmission and also lowering the relapse rate of pernicious malaria.¹⁰ Quinine or atabrine is active against the asexual stages of *P. falciparum* but fails entirely to devitalize the gametocytes. Obviously, if malignant tertian malaria occurs in a patient who will not be exposed to anopheline mosquitoes, the use of plasmochin is not essential.

A patient with chronic malaria is usually more difficult to cure than one with a primary case. Before a course of treatment is given, such patients should be allowed to go through a certain number of paroxysms to acquire some immunity against the infection.¹¹ This procedure is dangerous, however, with infections due to the highly invasive *P. falciparum*, unless the patient's blood can be examined daily to determine the number of parasites present and hence start treatment whenever multiplication begins to reach a dangerous level. Nevertheless, acquired immunity aids in securing a radical cure and should be utilized whenever possible in treating refractory cases.

PREVENTION OF SHOCK IN BURNS

THE recent trend in the prevention and treatment of shock resulting from injuries and burns has been to rely almost entirely on plasma transfusions. This procedure has behind it a considerable body of experimental data in animals, as well as a good deal of experience in clinical cases, and also seems to have a sound physiologic basis.

The early use of physiologic saline solution for the maintenance of blood volume in an attempt to prevent early deaths from shock was frequently resorted to in the past but has now been almost completely abandoned. It is even considered by many workers to be dangerous. A recent report indicating that saline solution when properly used may be superior to plasma is, therefore, of considerable interest and may result in a revision of some of the current concepts on this subject.

In a series of carefully controlled experiments, using standardized burns in mice, Rosenthal,¹ a pharmacologist in the Division of Chemotherapy of the National Institute of Health, has studied the effects of various types of systemic treatment on the immediate mortality from the burns. The procedure resulted in burns that were regularly fatal to the mice within forty-eight hours. He observed no benefit from the administration of substances designed to maintain or increase the blood pressure. These included epinephrine, posterior pituitary extract, adrenocortical extract and desoxycorticosterone acetate. All these substances were given subcutaneously following the burns.

Sodium chloride given by mouth or intraperitoneally caused a significant reduction in the mor-

tality. Intravenous administration was less effective, and an isotonic solution given by mouth was superior to hypertonic solutions. Potassium chloride, on the other hand, caused acceleration in the time of death, and when administered together with sodium chloride, it seemed to antagonize the effects of the latter. Calcium gluconate given orally was without effect. An isotonic glucose solution given by mouth showed only slight therapeutic action, whereas the administration of hypertonic glucose solutions or of water by mouth caused the animals to die sooner than the controls. A number of other sodium salts, including the acetate, succinate, bicarbonate and lactate, were found to be just as effective as sodium chloride. Of particular interest is the finding that mouse serum given intravenously was somewhat less active than equivalent volumes of physiologic saline solution given orally. Little effect was observed from the intravenous administration of hypertonic human serum albumin.

These experiments indicated to Rosenthal that the acute mortality following burns in mice is closely related to disturbances in the sodium-potassium balance in the body, as well as to the escape of fluids from the circulation. The former seems to be more important and may be casually connected with hemoconcentration and with the other effects usually ascribed to the loss of fluids in the burned area. This supports the view maintained by Scudder^{2,3} on the role of potassium as a toxic factor in shock, although his ideas are not generally accepted.

Certainly these findings are worthy of careful consideration. If similar results are obtained in large experimental animals, the application of these procedures to the treatment of patients seems warranted. If they prove to be of value in saving the lives of patients suffering from shock, this would result in the saving of large amounts of human plasma that are now used for this purpose.

MEDICAL EPONYM

BEARD'S DISEASE

A paper entitled "Neurasthenia or Nervous Exhaustion" was read before the New York Medical Journal Association by George Miller Beard (1839-1883), lecturer on nervous diseases at the University of New York. This paper was published in the *Boston Medical and Surgical Journal* (80: 217-221, 1869) and is quoted as follows:

The morbid condition or state expressed by this term has long been recognized, but the special name *neurasthenia* is now, I believe, for the first time presented to the profession.

... I have for some time been in the habit of employing the term *neurasthenia* to express the morbid state that is commonly indicated by the indefinite phrase nervous exhaustion.

The derivation of the term *neurasthenia* is sufficiently obvious. It comes from the Greek *neur*, and *asthenia* being literally interpreted signifies want of strength in the nerve.

... In regard to the pathology of *neurasthenia* we are compelled, in the absence of definite knowledge, to reason from logical probability.

My own view is that the central nervous system becomes dephosphorized, or, perhaps, loses some what of its solid constituents; probably also undergoes slight, undetectable, morbid changes in its chemical structure, and, as a consequence, becomes more or less impoverished in the quantity and quality of its nervous force.

... Among the special exciting causes of *neurasthenia* may be mentioned the pressures of bereavement, business and family cares, parturition and abortion, sexual excesses, and the abuse of stimulants and narcotics, and civilized starvation, such as is sometimes observed even among the wealthy orders of society, and sudden retirement from business.

R. W. B.

RESOLUTION ON THE DEATH OF EDWARD JOSEPH LEONARD

Dr. Edward J. Leonard, late visiting physician on the Medical Service of Carney Hospital, died on February 14, 1943, in his forty-second year, after an illness of many months. Dr. Leonard was born in Boston and was graduated from Georgetown College in 1922 and from Georgetown Medical School in 1926. He served his internship at Mercy Hospital, Baltimore. Shortly after completing his internship he was appointed to the Out-Patient Department of Carney Hospital as physician to the out-patients and later was advanced to visiting physician to the House Staff.

Salmonella infections were reported from: Boston, 1; Haverhill, 1; Holyoke, 1; Medford, 1; total, 4.

Septic sore throat was reported from: Boston, 6; Marion, 1; Wakefield, 1; Williamstown, 1; total, 9.

Tetanus was reported from: Brockton, 1; total, 1.

Trichinosis was reported from: Boston, 1; total, 1.

Typhoid fever was reported from: Boston, 1; Brockton, 1; Chelmsford, 1; Haverhill, 2; Norwood, 1; Quincy, 1; Winthrop, 1; total, 8.

Undulant fever was reported from: Adams, 1; Dartmouth, 1; Hopkinton, 2; Ipswich, 1; Rockport, 1; total, 6.

CORRESPONDENCE

A PHENOL SOLUTION FOR THE TREATMENT OF TRICHOPHYTOSIS ("ATHLETE'S FOOT")

To the Editor: About one and a half years ago, Francis (J. A. M. A. 117:1973, 1941) advocated the use of a mixture of phenol and camphor for the treatment of "athlete's foot." He warned that the mixture was caustic when applied to wet surfaces, and subsequent statements by others have indicated that it is too caustic for general use. After having been frequently afflicted with typical "athlete's foot" for many years, I concocted in 1930 a solution, also containing phenol, that has proved not only completely effective in combating this infection but also harmless even when applied to wet skin. The formula is as follows:

Phenol crystals (melted)	2 cc.
Ethyl alcohol (95 per cent)	2 cc.
Glycerin	4 cc.

The solution is applied by thoroughly rubbing the affected region with the end of a finger kept wet with the solution. The application is usually made twice daily, night and morning. In mild cases one application daily, or even less often, has sufficed. It can safely be made, and is probably most effective, immediately after the feet and lesions have been washed with soap and water. Itching is almost at once overcome by the first application. After the lesion has healed, an application once a week should be continued. Otherwise, in my own case, the condition recurs, sometimes within a few weeks. This may be because of reinfection, or of failure of the solution to kill spores. However, cure is so easily accomplished that many may prefer to await definite signs of recurrence, and then to repeat the treatment.

In mild cases healing is complete within a week; in severe cases within about three weeks. The surrounding skin never shows signs of damage, although it is always covered with some of the solution. Nor does the solution affect the finger that repeatedly applies it. Evidently the phenol does not penetrate deeply while still in high concentration.

The bottled solution retains its potency for at least two years. I have found that the effectiveness of the solution is almost, if not entirely, abolished when the amount of phenol is reduced by one half.

BOOK REVIEWS

Practical Survey of Chemistry and Metabolism of the Skin. By Morris Markowitz, M.D. 8°, cloth, 196 pp. Philadelphia: The Blakiston Company, 1942. \$3.50.

The study of the chemistry and the metabolism of the skin is a comparatively new field. Since Markowitz's book is the first in the English language dealing with the subject, it will be welcomed by everyone interested in this field.

A great deal of useful information is contained in this book despite its small size. Brevity is, in some instances, an advantage of the book because, by being brief, the author restricts himself to the presentation of essential facts. Some subjects, however, are treated too sketchily. The discussion of the blood chemistry of the xanthoma group, for instance, is inadequate. Some important chemical studies, like those by Nathan and Stern and by Dörfel concerning the electrolyte content of the skin in various dermatoses, are not even mentioned. Occasionally, the author in striving for brevity is too dogmatic, as, for example, in the statements that in the blood serum of patients with urticaria the nonprotein nitrogen is increased above normal and the chlorides are decreased and that in alopecia areata the serum cholesterol is decreased. In several instances the author breaks his stated resolution to omit hypotheses. He even discusses subjects entirely unrelated to dermatology, such as the clotting of the blood of Crustacea, the difference between Gentile and Jewish blood, and congenital (fecal) steatorrhea, to which he devotes a "chapter."

The extensive bibliography is a valuable part of the book. Its value would have been still greater if the titles of the quoted papers were given in all instances. The foreign references, unfortunately, contain literally hundreds of typographical errors.

American Jewish Physicians of Note: Biographical sketches. By Solomon R. Kagan, M.D. 8°, cloth, 304 pp., with 129 portraits. Boston: Boston Medical Publishing Company, 1942. \$5.00.

This book, a series of three hundred and sixteen brief biographical sketches, some of which are illustrated with portraits, is a supplement to the two editions of the author's previous volume, *Jewish Contributions to Medicine in America*, published in 1934 and 1939. A "Medical Chronology," from 1887 to 1942, is incorporated as an appendix. The subjects are well chosen, including such distinguished names as Isaac Hays, Abraham Jacobi, Simon Baruch, Samuel James Meltzer, Frederick Forchheimer, Howard Lilienthal, Max Einhorn, Simon Flexner, Milton Joseph Rosenau, Leo Loeb, Joseph Bolivar De Lee, Bela Schick and Morris Fishbein. The work is an impressive tribute to the contribution of the intellectual Jewish race to the progress of medical science in America. Perhaps the work might be made more useful and valuable by arranging the biographies alphabetically.

The Hand: Its disabilities and diseases. By Condict W. Cutler, Jr., M.D. 8°, cloth, 572 pp., with 274 illustrations. Philadelphia and London: W. B. Saunders Company, 1942. \$7.50.

In this book the author has made the ambitious attempt to discuss every injury and disease that may result in disability of the hand. With his wide experience in the

treatment of functional disturbances of the hind, the author has come closer to his aim than have the authors of most treatises. A more closely knit and a more useful reference book would have resulted if he had devoted his attention only to those things that are commonly seen and are known to result in serious disability. The chapters on acute infections and acute injuries are excellent; however, there is marked disproportion in the emphasis given to other conditions. Unknown and rarely seen diseases are described at length, whereas infantile paralysis and chronic arthritis are dismissed with a few paragraphs. Although great manual disability often results from these latter diseases, apparently the author is ignorant of this and of the voluminous literature that has been written on the rehabilitation of the hand following these diseases.

The illustrations are clear and for the most part well chosen. All but a few of them, however, have been borrowed from the writings of other men. A much stronger and more interesting book would have resulted if the author had drawn more on his experience and had supplemented this with illustrations of his own. Each chapter has a fairly complete bibliography of pertinent literature.

This treatise should prove to be a useful reference book to surgeons who are called on to treat disabilities of the hand.

Gynecology with a Section on Female Urology. By Lawrence R. Wharton MD. 8°, cloth 1006 pp. with 444 illustrations. Philadelphia and London: W. B. Saunders Company, 1943. \$10.00.

This book is divided into sixty-five chapters, a number of them being preceded by a synopsis, and each being followed by an essential bibliography.

The chapter on anatomy is well done, its illustrations have been borrowed largely from other works, but were wisely chosen. The chapter on embryology is concise and clear, the subject of female hormonology is brought up to date and as here presented is readily within the grasp of the medical student. Twenty-seven pages are devoted to menstruation, functional uterine bleeding and hyperplasia of the endometrium are fully discussed, and dysmenorrhea is extensively covered from the standpoint of etiology and of treatment, conservative treatment being emphasized. The treatment of the menopause, both natural and artificial receives due consideration. A chapter is given over to the sympathetic nervous system in gynecology and female urology, and the operation of presacral neurectomy is clearly illustrated. The injuries of childbirth are graphically explained, their nonoperative and operative treatment are described and methods of operation are suggested those advocated by George Gray Ward receive considerable prominence. The importance of free dissection and the use of fiscal structures are emphasized both in the text and the illustrations.

The author assigns 37 pages to uterine prolapse. Here special emphasis is placed on four methods, namely, the interposition operation, the Ward modification of the Mayo vaginal hysterectomy, Richardson's composite operation, the parametrial fixation, or the Manchester operation. Misplacements of the uterus are treated conservatively in uncomplicated cases, whereas suspension operations of which a number are described are reserved for complicated ones.

The newer methods of treatment in pelvic infections—gonorrheal, tuberculous and puerperal—are extensively discussed and illustrated. Diseases of the vulva, the vagina and the uterine cervix are well brought out, with a chapter on pruritus. Genital fistulas, both urinary and fecal, are mentioned, and a plan for their repair is satisfactorily outlined.

The section on carcinoma of the cervix, which covers its classification, histology, diagnosis and treatment, is especially well done, and treatment of carcinoma of the cervix in pregnancy is in accord with recent views. Sixty-four pages concern diseases of the uterus, myomas being freely discussed and illustrated, and uterine sarcoma receiving due consideration. In the management of carcinoma of the endometrium, panhysterectomy with removal of the adnexa and a cuff of vagina is recommended, whereas irradiation is reserved for poor surgical risks. Irradiation before surgery is advised whenever feasible, since many patients are thereby so improved that operation becomes possible. It is used postoperatively as indicated.

There is a chapter on hysterectomy abdominal and vaginal, in which the technique of abdominal hysterectomy is profusely illustrated. Individualization of cases is recommended, and a conservative approach is advised in the choice between supracervical hysterectomy and panhysterectomy for benign uterine lesions. Diseases of the fallopian tubes are adequately described in a separate chapter.

A great deal of space is given to tumors of the ovary. The historical section makes interesting reading; the common rare tumors are described and the classification given is simple and easily comprehensible.

All the known tests and methods of treatment in connection with sterility are thoroughly explained and included in an 18-page chapter on abortion not commonly found in the average textbook on gynecology. There can be no valid objection to its inclusion since the gynecologist is constantly called on to treat abortion. In this book it is covered as completely as it is in most books on obstetrics.

A favorable impression is gained from the interesting chapter on postoperative care, and the gynecological part of the book is concluded by a discussion of the normal hygiene of healthy women.

The second section covers anatomy and methods of urologic diagnosis, and the relation of the urinary organs to the pelvic organs is stressed. In the description of cystoscopy the Kelly air cystoscope is used. It is true that this method developed at the Johns Hopkins University School of Medicine is still extensively employed there for examination of the bladder and catheterization of the ureters but most investigators trained elsewhere prefer the water cystoscope, realizing that the lithotomy position employed with the water cystoscope is more comfortable for the patient than is the knee-chest position in which she is placed when the air cystoscope is used. This section on urology is complete and well illustrated, and may serve as ready reference.

There is but little in this book with which the teacher of gynecology would not agree. It is well prepared and illustrated and should be easily understood by the medical student. For the general practitioner it affords a ready reference to the important problems of gynecology including female urology, and it deserves a place in the library of the specialist.

Blood Substitutes and Blood Transfusion. Edited by Stuart Mudd, M.D., and William Thalhimer, M.D. 8°, cloth, 407 pp., with 97 illustrations, 6 charts, 60 tables and 6 graphs. Springfield, Illinois: Charles C Thomas, 1942. \$5.00.

This book is a compendium of work presented at a symposium in 1941. The preliminary discussions of the pathologic physiology of shock consist of reports of experimental observations by several authorities. These are well-known studies but in fragmentary form and not meant to be comprehensive; rather they are introductory to the many other chapters of the book concerned with methods of blood-volume restoration. These chapters therefore are not of too great importance in themselves because they are so incomplete and by no means up to date.

The various succeeding chapters contain a large amount of detailed technical information on the preservation, storage, freezing and drying of plasma, which should be useful to hospitals, defense centers and so forth. However, they are not especially useful for the individual clinician.

There are many good discussions of the chemistry and separation of plasma proteins. A report of preliminary work on hemoglobin as a plasma protein substitute is presented. The preliminary clinical testing of beef albumin encouraging enough to warrant further trial is recorded, but the results of more recent trials are not available. Early reports of the utilization of casein digests to form plasma protein are to be found in the discussion, but these have been greatly supplemented in the current surgical literature. The necessity for good large-scale methods of providing adequate supplies of properly processed plasma or effective plasma substitutes is stated from the civilian and military points of view. There is an excellent discussion of bacteriologic problems involved in the collection and storage of whole plasma. Likewise, the problems of storage of whole blood are described, including the biochemical, morphologic and immunologic changes that occur in stored blood. The discussion of special aspects of blood type in whole-blood transfusion is extremely valuable, and includes a consideration of universal donors, of neutralizing type-specific antibodies, of improved methods for typing serum and of the Rh factor.

The clinical reports on the use of stored plasma lend credence to the general knowledge that the various kinds of stored plasma are safe to give. Practical problems are discussed in case reports. Because of the detailed technical information, the book should be useful for persons or institutions interested in establishing a blood bank or plasma supply. And it should be helpful to physicians or surgeons because it presents a good outline of the problems of blood substitutes and because it gives a good discussion of methods to establish the compatibility of whole blood. It contributes little to a consideration of the shock problem or of the usefulness of blood substitutes in shock since most of the reports are too preliminary and there are no extensive clinical or experimental data.

In general, this book has the faults and advantages of a compendium. It is uneven—many sections bear little weight because of the preliminary nature of the reports, and many sections are of interest to a few only because of their technical character. On the other hand, it has the advantages of containing a good deal of in-

teresting and useful information that is easily reached by reading the appropriate section.

Diseases of the Skin. By Frank Knowles, M.D., Edward F. Corson, M.D., and Henry B. Decker, M.D. Fourth edition. 8°, cloth, 621 pp., with 272 illustrations. Philadelphia: Lea and Febiger, 1942. \$7.00.

In the fourth edition of this textbook, Drs. Edward F. Corson and Henry B. Decker have been added as co-authors.

The book begins with an introductory chapter dealing with the anatomy, physiology, diagnosis and therapy of skin diseases. Fourteen chapters describing the various classes of cutaneous disease, with a discussion on new conditions, under twenty-seven additional headings, have been added in this edition. A short reference to vitamins in relation to skin diseases and the use of sulfonamide drugs in therapeutic measures are included in the introductory chapters.

Tropical skin diseases are discussed, and the chapter on the treatment of syphilis is especially valuable to the general practitioner since practical plans for the therapy of all stages of the disease are presented in detail.

The book, although relatively small for a textbook, furnishes a description of all the skin diseases in a more concise form than is found in the larger textbooks on dermatology.

The bibliography consists of a limited number of references, and twenty-one new engravings have been added. The photographs are unusually clear, but there is a lack of histologic plates, which many readers are especially interested in today since dermatopathology is stressed as an important field in the study of skin lesions.

This volume is recommended as a textbook for the medical student and will be particularly useful to the practitioner of medicine because it gives the necessary information in a readable, concise form.

Mark Pfeiffer, M.D. By John Weld. 8°, cloth, 324 pp. New York City: Charles Scribner's Sons, 1943. \$2.75.

This is a novel of a young doctor from the Middle West who gets his final training in Chicago and marries a wealthy, snobbish, unprincipled woman in place of a fine nurse, his first choice. Finally the marriage breaks up, as it was bound to do, and he returns to his first love. This is a rather straightforward, simply written novel with a medical background. The characters are not particularly well drawn and the story is one that will not excite interest. There is too much emotionalism, drinking, marital infidelity and bad language.

Of slight interest to doctors, however, is the depiction of Howard Kendrick, a neurosurgeon from Boston. This is quite obviously a portrait of the late Harvey Cushing. The hero of the book comes to work with Kendrick for a year, and in the following chapters there are remarks and some action characteristic of one aspect of Cushing's life; however, the author has missed much of the real man behind Cushing's mannerisms. The hero of the story is impressed by Kendrick's character and his future life is guided by what he unconsciously absorbed under Kendrick's tutelage. As this book is dedicated to Dr. Loyal Davis, it is presumed that he may have been helpful to the author, as a former student of Dr. Cushing.

PULMONARY EMBOLISM DUE TO QUIET VENOUS THROMBOSES AND SIMULATING CARDIAC AND PULMONARY DISEASE

JOHN HOMANS, M.D.*

BOSTON

PULMONARY embolism is often caused by quiet thrombosis in the legs. As a complication of operation, injury or illness, this accident is well recognized. But embolism due to quiet or silent thrombosis may also occur in seemingly well persons. Before any signs of thrombosis appear, it may recur again and again or may prove fatal at a single episode. Embolism from such a thrombosis is more apt to cause repeated pulmonary infarction without fatality than that which complicates operation, accident or illness. Yet it may end fatally. Its symptoms sometimes imitate coronary occlusion and sometimes pulmonary disease. It may even take on one appearance or the other in successive episodes in any one patient.

For some years, Dr. Paul D. White has been calling attention to the frequency of pulmonary embolism and infarction. In a recent paper, which reviews twenty years of his personal experience, he¹ indicates that the medical profession has been backward in paying attention to these serious accidents. He notes his own rapidly increasing number of observations in cases that he would formerly have diagnosed as congestive heart failure or pneumonia. In respect to the simulation of heart disease by embolism, White finds that in 75 definite cases of embolism, most of which he has observed during a recent ten-year period, 28 simulated and 47 complicated heart disease. He finds clues to the diagnosis of embolism in periodic attacks of faintness or dyspnea or prostration, or in attacks of unexplained fever and leukocytosis or even jaundice (from hemolysis of the infarct and an engorged liver). It will be noted that these are not conventional symptoms of pulmonary embolism.

The very fact that White, as a cardiologist, sees cases in consultation that other physicians have diagnosed as angina, coronary occlusion or pneu-

monia has given him the opportunity to distinguish many cases of embolism masquerading as heart disease, and he has put up to surgery the task of discovering and removing the source of embolism in such circumstances. He has squarely stated the problem when he says, "Peripheral phlebitis was evident in only a few cases, but it is probable that the majority might have shown such a lesion if we could have explored the veins; at least, that is the lesson to be derived from the post-mortem findings at the Massachusetts General Hospital, where 70 per cent of the medical pulmonary embolism cases have phlebitis that gives no evidence of its presence."

In support of this aspect of the subject, Hampton and Castleman,^{2,8} from their exhaustive combined roentgenologic and pathological study of pulmonary embolism and infarction, are finding these lesions in increasing numbers. They hold that there need be neither a combination of pleural pain and blood spitting nor any obvious source of embolism, but that given any clue, and with roentgenologic evidence, a diagnosis may be made. One of their conclusions is pertinent here. They say, "In view of the fact that one-third of the cases of pulmonary infarction occur in patients who have not been operated upon and who have no demonstrable cardiac disease, it is important to consider pulmonary infarction in the differential diagnosis of pulmonary disease in *ambulatory patients* [italics mine]."

This paper is a sequel to one by me¹ published in this journal in 1934 under the title "Thrombosis of the Deep Veins of the Lower Leg, Causing Pulmonary Embolism." In 3 of the 4 cases discussed in that paper, there was an element of trauma; 2 patients, not suspected of harboring a thrombosis, died of pulmonary embolism, and 1 was treated by division of the femoral vein in order to prevent a possible embolism. The fourth patient, who recovered without operation,

*Clinical professor of surgery, emeritus, Harvard Medical School; acting surgeon in charge of circulatory diseases, Peter Bent Brigham Hospital.

reappeared with a second idiopathic quiet thrombosis in 1939, sixteen years after his first, but in the opposite leg. Eleven cases form the basis of discussion, in all of which trauma, operation and serious illness were absent or insignificant factors. "Idiopathic" is a poor term, but it connotes "of unknown origin" or "without satisfactory explanation." Barker⁵ used it in 1936 in a paper describing thrombophlebitis in ambulatory patients, but it was an old term then. Actually, the fact that an injury, operation or illness precedes thrombosis explains nothing, since no one knows why ninety-nine such episodes cause no thrombosis and the one hundredth a dangerous process. But to throw oneself into the frame of mind which admits that thrombosis in the deep veins of the legs may occur in anyone at any time, one must cease to believe that *any* recognizable etiologic factor need exist.

Quiet thrombosis, or so-called "phlebothrombosis," is a noninflammatory, reactionless process. It takes place in the deep veins of the legs, usually below the knees. In its dangerous stage, it causes little venous obstruction. Though it may occur at any age from adolescence to senescence and in persons of various physical types, it is most commonly seen in the sixth and seventh decades and in fat or fattish patients. Thus it has much the same incidence as the outspoken inflammatory thrombophlebitis, or phlegmasia alba dolens, to which actually it is related.

The peculiar and dangerous quality of a quiet venous thrombosis lies in its decided tendency to form a loose, soft, detachable thrombus. It does not necessarily form such a propagating thrombus. Indeed, it is true that thromboses often heal without accident and, occasionally perhaps, without being noticed. Many develop into an obstructive, outspoken thrombophlebitis.* The explanation of the lack of statistics warning the profession of the incidence of quiet thrombosis and consequent embolism lies in this, that the more silent the process, the greater the danger of embolism. This is almost a law. A fatal pulmonary accident may come from a leg that even those most familiar with venous thrombosis must consider normal, and by contrast, the great swollen leg of thrombophlebitis almost never causes embolism. Statistics based on *recognizable* thromboses are thus nearly useless. In the quiet process, some part of the thrombus is not adherent or is only very lightly

adherent to the vein, being partly or wholly free to float away; whereas the inflammatory thrombus is fixed by a local reaction in the wall of the vein. One should think of a quiet thrombosis as consisting of a local process occupying perhaps only a few inches of a vein, one of many among the great muscles of the calf, but possibly having a loose, soft tail that floats in the popliteal and femoral veins. On this basis, why expect to discern outspoken or indeed any physical signs in the leg? Barker et al.,¹⁰ of the Mayo Clinic, have published figures that indicate that one person in twenty in whom thrombosis is recognized will suffer from a pulmonary embolism of some degree, but these figures suffer from the defect that I have just indicated.

I propose, therefore, to deal here with pulmonary embolism as a single or repeated episode, usually from so silent an idiopathic thrombosis that the pulmonary infarct is apt to be mistaken for or confused with a coronary occlusion, angina or pleurisy. But because embolism is not the necessary or even the usual result of a quiet, deep lower-leg thrombosis, and because treatment of thrombosis, whether or not it has already caused embolism, is required, it is necessary to consider briefly the three courses that the original thrombosis may pursue, which are as follows: recovery without extension; development into phlegmasia alba dolens; and formation of a propagating thrombus with pulmonary embolism.

Recovery without extension or embolism. This may take place without operation, though among 5 cases (six episodes) so treated by me, elevation and rest failed three times (signs of thrombosis reappeared on resumption of an active life) and division of the femoral vein was then required. Two patients recovered without operation; in one of these, however, the disease appeared in the other leg sixteen years later, when conservative treatment was followed by recurrence, and at operation a soft thrombus was sucked out of the femoral vein. Considering the frequency with which embolism is associated with any one quiet thrombosis, not to speak of recurring thrombosis, this short series gives evidence in favor of immediate operation without a trial of conservative measures.† Such treatment was used only twice. However, no deaths occurred among the few patients conservatively treated, which was perhaps good luck.

Development into femoroiliac thrombophlebitis (phlegmasia alba dolens). Evidently this development is not often observed. Only twice have I

*It is now fairly well established, through the work of Rössle,⁶ Bauer,⁷ & Frykholm⁸ and others, that the great majority of venous thromboses in the legs, of all types, begin in the calf and foot; in fact, that only 10 per cent of all thromboses in the femoral vein are unassociated with deep thrombosis below the knee. Thus the quiet peripheral disease must frequently develop into the obstructive, inflammatory type. Bauer has traced this development in venographic studies. The idea is contrary to the long accepted belief that a femoroiliac thrombophlebitis usually occurs independently of any peripheral process.

†Since postoperative and post traumatic thromboses are not under discussion here, it is unnecessary to quote Fine and Sears¹¹ or Welch, Faxon and McGahey¹² in support of routine division of the femoral vein. Probably, however, most of the lessons learned from cases of postoperative thrombosis apply here, that is, to cases of idiopathic thrombosis that have not yet given rise to embolism.

noticed it clearly. Yet the Swedish investigators, especially Bauer,^{7,8} are sure that it is common, and Conner,¹⁸ in discussing his experiences with typhoidal thrombophlebitis, speaks of the frequent observation of early signs in the foot and calf before the full-blown swelling of phlegmasia alba dolens occurs. One certainly sees cases in which embolism precedes this outspoken state, that is, during an early, quiet stage.

Formation of a propagating thrombus with pulmonary embolism. This outcome is covered by the 11 cases to be presented in some detail, and with these will be discussed, incidentally, 6 cases of embolism arising from thrombosis due to injury, illness or an old thrombophlebitis. Actually, these latter behave in every way like the idiopathic sort except, perhaps, that, following an old femoroiliac thrombophlebitis, the recurrent episodes of embolism may be spread out over particularly long periods, even over many years. Postoperative thrombosis, and embolism are not considered here at all.

* * *

The following 11 brief case reports will give some idea of the nature of the problems presented and the results obtained.

CASE 1. R. M. A., a 61-year-old man, had previously been well. There was repeated embolism over a period of 3 months, at first suggestive of coronary occlusion, but with a negative electrocardiogram, and later of right-sided and left-sided infarctions. Examination of the legs was negative until 1 week before operation. There was a positive dorsiflexion sign and faint cyanosis of the left foot on standing. A bilateral process was suspected that extended above the groin on the left, as indicated by long striding disease and a cyanotic left foot.

Operation consisted of section of the left common iliac and right superficial femoral veins. A serious embolism occurred before the left iliac vein was approached. There was no thrombus at the level of division. A hurried section of the right superficial femoral vein may have caused failure to observe a thrombus in the common femoral vein. A small embolism developed on the 4th postoperative day. There was recovery with no further embolism and with excellent function. There was a slight swelling of the right leg on the side of the femoral division.

CASE 2. W. L. S., a 56-year-old man, had possible old biliary disease. There had been repeated attacks of subcostal pain over a period of 6 months. Coronary occlusion was suspected but not proved. There was a fall in blood pressure. Patchy consolidation of both lungs was observed. Four weeks before operation tenderness developed over the right femoral vein at the groin, without edema. Later there was a positive dorsiflexion sign, but no cyanosis. A right-sided process as high as the inguinal ligament was suspected.

Operation consisted of section of the right common iliac vein. There were no further attacks. Function of the right leg was excellent. There was subsequent development of acute cholecystitis and stone in the common duct.

CASE 3. C. W. Y., a 53-year-old woman, had previously been well. Repeated attacks of breathlessness and faintness had occurred over a period of 3 months, without pain. Examination of the thorax (by x-ray) and legs was negative until 4 days before the first operation, when the left foot became faintly cyanotic on standing. During the following days, further serious attacks of breathlessness and faintness occurred. The dorsiflexion sign in the left leg became positive. There was no edema. By x-ray, there was considerable pulmonary infarction of the right lung. The diagnosis was repeated pulmonary embolism from a quiet process in the left leg.

The first operation was section of the left superficial femoral vein. No thrombus was found at this level. Increasing dyspnea and signs of thrombosis in the right leg during the next few days led to division of the right superficial femoral vein, and again no thrombus was found. During the next 2 weeks, rising venous pressure and a wide shadow of the superior vena cava shown by x-ray examination warned that the pulmonary artery was obstructed. Cor pulmonale developed. The patient was heparinized for several days before her death.

Post-mortem examination showed the pulmonary artery and its branches to be loaded with emboli of varying sizes and ages. From the profunda femoris of each leg a healed thrombus projected into the common femoral vein. The last emboli might well have come from this source.

CASE 4. W. W., a vigorous 34-year-old man, had a bad family background of thrombosis and embolism. During the past year, three episodes of pleuritic pain and bloody sputum had occurred. X-ray examination revealed several pulmonary infarcts. The right leg, otherwise negative, gave a positive dorsiflexion sign. A venogram excited a rapid spread of the thrombosis.

Operation consisted of division of the right superficial femoral vein. No thrombus was found at this level. The patient was heparinized. Following withdrawal of the heparin, thrombosis in the calf again became aggravated. There was recovery with excellent function of the leg. No further embolism occurred, but 16 months later there were signs of thrombosis in the opposite leg.

CASE 5. C. A. G., a 55-year-old man, had a doubtful history of a superficial thrombosis 15 years previously. The first episode, 2 months previously, consisted of a fugitive lameness in the left calf, followed by an unexplained cough. Later, there were several attacks of cough and dyspnea and finally hemoptysis. A positive dorsiflexion sign was noted in the right leg. There was no swelling or cyanosis.

Operation consisted of division of the right superficial femoral vein, but no thrombus was found at this level. There was recovery with excellent function and no further embolism.

CASE 6. H. M. B., a 49-year-old man, had had two episodes of violent subcostal pain on successive days 3 weeks previously, with dyspnea and cough. There was thrombosis in a varicose vein of the right leg, associated with cyanosis and slight swelling of the whole right leg, and indicating thrombosis as high as the inguinal ligament.

Operation consisted of division of the right common iliac vein, no thrombosis being found at this level. There was recovery with excellent function and no further embolism.

CASE 7. T.A.W., a 55-year-old man, was suffering from a moderate arteriosclerotic deficiency. Three years previously he had experienced a supposed coronary occlusion, from which he had made a good recovery. One week before operation there was sharp pleural pain on the left side. X-ray examination revealed a pulmonary infarct. There was a positive dorsiflexion sign in the right leg, but no cyanosis or edema.

Operation consisted of division of the right superficial femoral vein and periarterial sympathectomy. No thrombus was found at this level. There was recovery with excellent function and no further embolism.

CASE 8. R.E.F., a 47-year-old man, had suffered pleural pain and hemoptysis 10 years previously, following pain in the left calf with local swelling. He was thought to have tuberculosis. Five years previously a superficial wandering phlebitis was cured by high section of the saphenous vein. Over the last few years there had been recurring pain and lameness in the left calf. The patient had had a recent attack of pain, soreness and slight cyanosis of toes, lasting for 10 days. There was a positive dorsiflexion sign. No tenderness was found over the femoral vessels.

Operation consisted of section of the superficial femoral vein. No thrombus was found at this level, but a feeble flow of blood suggested thrombosis just below it. There was good recovery with excellent function.

CASE 9. F.B., a 57-year-old man, had previously been well. Two months previously hemoptysis occurred without warning. One month later the left ankle was found to be swollen, the leg lame, and the calf tender. Conservative treatment was followed by recurrence of local signs.

Operation consisted of section of the superficial femoral vein. There was good recovery with some cyanosis of the lower leg. No further embolism occurred.

CASE 10 (previously reported³). H.L., a 55-year-old man, gave an early history of mild rheumatic fever. On the day that he noticed swelling and discomfort of the right lower leg, he was in a minor automobile collision. From that moment until his death 6 days later, he was short of breath and decidedly cyanotic. The right leg below the knee was moderately swollen, but local swelling as well as general cyanosis improved up to the moment of his death.

Post-mortem examination revealed a 30-cm. embolus that had been floating in the pulmonary artery until beginning organization and fixation had finally obstructed the vessel. Embolism must have occurred at the moment of the automobile collision. The source of embolism was a diffuse, deep thrombosis in the deep veins of the calf. There was a similar process in the veins among the thigh muscles.

CASE 11. E.D., a 63-year-old woman, had had a superficial thrombosis in the veins of the thigh for 3 weeks. There were sudden breathlessness, faintness and collapse at the end of this time. Three days later, the legs were negative for all signs of thrombosis, except for a tender mass in the left groin, which was proved at operation to be a canalized fresh thrombus at the root of the great saphenous vein. A propagating thrombus had probably broken off in the femoral vein.

Operation consisted of section of the great saphenous vein. There was recovery with no further embolism.

Among the 11 idiopathic cases, there were 9 men, and in the whole group of 17, only 3 women, yet when women were affected, the result was always serious.

The ages of the combined groups ran from twenty-eight to sixty-three. Only 3 of the idiopathic group were under fifty and the 2 patients who died of embolism were, respectively, fifty-three and fifty-five. In the secondary group, the 1 patient who died of embolism was fifty-three. In this same group, a man of twenty-eight developed a thrombosis as a result of whooping cough and suffered a pulmonary infarction, but he had attempted to cure his disease by playing squash rackets.

Multiple embolism occurred six times in the idiopathic group. There seems to be no rule as to the seriousness of the individual episodes. In 1 case, after many small embolisms, spread out over three months, had left no trace in the lungs by x-ray examination, an accumulation of many fragments, coming from both lower legs and perhaps from the veins of both thighs, finally, in spite of division of the femoral vein, plugged the pulmonary arteries, with a fatal result. With one notable exception (Case 1), in the other 5 cases of multiple embolism there was little damage, and all patients recovered after vein division. One single embolism was fatal. Small and rather harmless single embolism occurred 3 times.

In the supplementary group, multiple embolism occurred four times. In 3 such cases, all of thrombosis following an old femoriliac thrombophlebitis, vein division was followed by recovery. The fourth, an obscure case in which infarction followed an acute enteritis, was subjected to heparinization without operation, and the patient died of pulmonary embolism. In the fifth and sixth cases, infarction was small and unimportant.

As between cardiac and strictly pulmonary symptoms, it would seem that when an embolus causes a true anatomic, pulmonary infarct, a pleuritic type of pain usually results. Then there is little suggestion of angina or a coronary occlusion. But emboli do not necessarily obstruct either large or small pulmonary vessels, at least in the sense that they create a bloodless, airless pulmonary area visible on roentgenography, and so they are apt to cause substernal agonizing pain, or fainting, or breathlessness, or some combination of these symptoms. Cough and expectoration of blood may occur after any initial symptom or without any earlier symptom.

The electrocardiogram is helpful to the cardiologist. In pulmonary embolism, appearances characteristic of coronary conclusion are absent. A

normal electrocardiogram is, of course, consistent with pulmonary embolism, but serious obstruction to the pulmonary circulation by emboli, causing embarrassment to the right side of the heart—that is, *cor pulmonale*—gives characteristic signs. It is necessary in that case to be sure that the emboli have not arisen in the right heart itself.

X-ray study is remarkably helpful in making a positive diagnosis of pulmonary infarction. Yet a clear lung field is consistent with serious and repeated embolism.

Failure of even massive emboli to cause death for many days, or even for weeks and months, has appeared twice in the idiopathic series. In one case,* that of a man of fifty-three, slight cyanosis and breathlessness were initial symptoms. During the following six days, recovery seemed to be taking place, but at the end of this time a typical embolic death occurred. Autopsy showed a partly organized embolus, a foot long, floating in the pulmonary artery, which it had finally obstructed. In another case a woman of fifty-three, after repeated embolism for three months and an unsuccessful bilateral division of the femoral vein, finally died. For most of the last weeks of her life, she had been breathless. *Cor pulmonale* was evident, but the lung fields, as previously told, for a long time, were clear. Autopsy showed quantities of organized thrombi fixed in the pulmonary arteries. Here again, full obstruction was greatly delayed.

The effectiveness of vein division. Among the 11 idiopathic cases, division of the femoral, external iliac or common iliac vein was practiced in 10 patients. In the eleventh, as is related in the protocols, the patient's cyanosis gave rise to a suspicion of some cardiac disorder, and operation was not attempted. This was fortunate; for the great embolus was already in the pulmonary artery.

In 1 of the 10 cases subjected to operation, as already told, many emboli had already entered the pulmonary artery before operation was undertaken. Then the superficial femoral veins of both legs were successively divided and, there being no thrombus in the femoral, distal to the profunda, there seemed no need of interrupting the vein at a higher level. However, as the subsequent autopsy showed, a thrombus, starting in the profunda, had already entered each common femoral vein or subsequently did so. Therefore, when embolism is of long standing and perhaps when thrombosis is thought to have been going on for weeks or months, the vein certainly ought to be divided proximal to the profunda or even higher. The point will presently be discussed. In any event, among the 11 cases, this was the only one, curable

perhaps by surgery, in which death occurred and further embolism was not prevented.

In the secondary group, all the patients subjected to surgery recovered. One patient, treated by heparin alone, died.

The level of vein division. In the usual case, when one or more episodes of embolism have occurred and local signs point to thrombosis in one leg, it is sufficient to divide the superficial femoral vein. As this is done, an examination should be made to detect thrombosis at the level of division. If no thrombus is present below the profunda or at the level of the profunda, division of the superficial femoral is satisfactory. One is also led to be satisfied with this procedure because it disturbs the venous return very little; whereas, if the common femoral vein is divided, proximal to the profunda, serious congestion and swelling often follow, especially if no old thrombophlebitis has preceded, building up a collateral venous pathway.

There are two possible sources of accident in case of division of the superficial femoral vein in the leg showing clinical signs of thrombosis: a separate deep thrombosis in the thigh, already present or to occur later, may give rise to future embolism; there may be a separate, silent thrombosis in the opposite leg.

In respect to the first of these accidents, Frykholm⁹ has shown that an independent thrombosis not at all rarely starts in the deep muscular veins of the thigh, whence it enters the common femoral by way of the great profunda branches. How often this complicates a deep thrombosis originating in the lower leg is not known, for when one finds a thrombosed, partly obstructed profunda in exploring thrombosis of the superficial and deep femoral veins, there is no saying whether thrombosis has started independently in the profunda or whether a retrograde thrombosis has backed up into it. I am inclined to think, therefore, that in old thrombotic processes attended by embolism, one should always divide the common femoral vein above the profunda or go even higher. This latter procedure I shall presently discuss.

In respect to the second possibility—namely, that the second leg is involved—this is anyone's guess. I have not as a routine explored the femoral vein of the second leg when that leg shows no sign of disease and when the evidence for thrombosis in the leg already subjected to operation is good. Nevertheless, a silent process in the second leg may actually be the source of embolism at the time the first is subjected to operation. For example, if embolism is still taking place when the first leg is already considerably swollen as a result of a process now becoming obstructive in the veins

*This case was reported in the previous paper.

of the groin and pelvis, this really exonerates the swollen leg; for embolism seldom occurs from an obstructive thrombosis or thrombophlebitis. Therefore, the place to look for the *present* source of embolism is the second, or innocent-appearing, leg. This perhaps is the time to use venography. But I should be perfectly willing to explore and divide the superficial femoral vein of the second leg without venography under the conditions just outlined.

Division of the common or external iliac vein. This procedure has been carried out eight times in the combined series. The right common iliac vein has been divided six times, the left common iliac and the left external iliac each once. I propose, in a subsequent publication, to make a special study of these operations. It is enough to say of them here that: division of the common iliac is the operation of choice in processes of considerable age when thrombosis is believed to have occupied, without altogether obstructing, the common femoral vein; division of the common iliac in particular offers a better collateral venous return than division of the common femoral; division of an iliac vein is not much harder to perform than is division of the common femoral, since it can be carried out extraperitoneally; and the higher division gives the patient and surgeon an assurance of safety, lacking in even a common femoral division, since, almost invariably, the thrombosis has not mounted to the level of operation. The above is especially applicable to right-sided processes, for not only do these tend to mount less high than left-sided ones, but the right common iliac vein lies lateral to the artery and is easily accessible by an extraperitoneal approach. As for the left-sided thromboses, I have been in considerable doubt as to the advantage offered by interruption of the common iliac vein. However, experience has assured me that when a comparatively old process is already present at the groin, the operation is decidedly worth while. In the first place, one can usually divide or ligate the left common iliac vein proximal to the thrombus; and in the second, although the vein lies median to the artery and rather over the edge of the pelvis, it is still reasonably accessible by the extraperitoneal operative approach. The chief difficulty that I have encountered lies in dealing with a friable vein that has been the seat of an old inflammatory

thrombophlebitis. Adherent and easily torn, its deep situation makes its isolation a delicate matter. Doubtless further experience will throw light on such problems.

SUMMARY

An account has been given of 11 cases of quiet thrombosis in the lower limb causing pulmonary embolism in ambulatory patients. With these cases are discussed 6 others of similar character but in which an old thrombophlebitis, an injury or an illness had preceded the thrombosis.

Consideration of all these cases shows that since pulmonary infarction and embolism often simulate cardiac and pulmonary disease, in ambulatory patients otherwise well, they must be considered in the differential diagnosis of many acute and recurrent thoracic disorders.

It may reasonably be concluded from this short series of cases that: repeated embolism, associated with quiet thrombosis, is not rare; the dangerous or fatal quality of any one process is unpredictable; operative treatment, to secure interruption of the thrombosed vein proximal to the source of embolism, is always indicated; conservative treatment, even if not followed by further embolism, is unlikely to prevent continuance or recurrence of the thrombosis; and the use of heparin does not protect against repeated embolism and a fatal outcome.

THE HEALTH EXAMINATION OF ADOLESCENTS*

J. ROSWELL GALLAGHER, M.D.†

ANDOVER, MASSACHUSETTS

DURING recent years there has been an ever-increasing interest in health examinations,¹ but most of the emphasis has been put on the care of infants, children at the grade-school level, college students, and adults who have reached the age when the disorders of senescence may be expected to develop. School health examinations are usually confined to a limited inspection of children in the primary grades; it is unusual, except in a few preparatory schools, to find adequate health examinations given to students at the high-school level. This relative neglect of the adolescent becomes more serious because of the unfortunate division of responsibility for his care that now exists between the pediatrician and the physician who ordinarily cares for adults: over a period of a few years during which physiologic and psychologic changes are at their height, the adolescent does not have either the advantage of a school health examination or the special attention of a physician whose primary interests and training are immediately concerned with the peculiarities of adolescence.

Another reason for the widespread neglect of health examinations in the adolescent group is the apparent health of most of these persons: their appearance seems to have led many to believe that a careful health examination will be fruitless. It seems obvious that, apart from the educational value of the annual health examination,² it is also valuable because it both permits the discovery and correction of any defects that interfere with optimal function and provides an opportunity of making the subjects cognizant of any irremediable conditions that might subsequently exclude them from certain civil or military careers.

The importance of such examinations can be readily appreciated by the study of the findings now being made by those who have examined young draftees, and this report, which concerns the findings at the health examination of 910 preparatory-school boys of the thirteenth-to-eighteenth-year age group, appears to furnish further evidence of the value of such a procedure. It should be remembered that the data are obtained from members of an economically privileged group, and that consequently the percentages for those conditions that may be affected by economic status are probably

lower than those that a survey of the general population would supply. In addition to a discussion of the findings at the health examination, a note concerning functional physical fitness is included: it seems desirable to include an estimation of the ability of each subject to perform and to recover from brief exhausting work in any thorough examination, and to avoid the error of basing one's estimate of fitness only on observations made when the subject is at rest.

METHOD OF EXAMINATION

Each year about 725 students are examined; about 250 of these have entered the institution for the first time and are given their initial examination. It has been found possible to examine about 50 of these students in a period of four hours and a half; an attempt is made to schedule twice as many boys who have been examined on previous years as new students. A student is first given his examination sheet, his name and age are recorded, and he is sent to a trained technician for an eye examination. At this examination his vision with and without glasses, his vision through a + 1.50 lens and his muscle balance at both near and distant vision are determined and recorded on the examination sheet. The technic used is similar to that recently described by Sloane.³ A nurse experienced in the use of a II-A audiometer tests the hearing of each new student and of all others known to have had ear disease or impairment of hearing in the past. Recently it has been difficult to obtain dental assistance, but when possible bite-wing x-ray examination and a manual examination are included as the next procedure. The student then disrobes and goes to an assistant who records his weight, height and color vision.⁴ He next goes to a physician who inspects his skin, nose and throat and examines his heart, lungs, abdomen and extremities in the conventional manner and sees that a urine specimen is collected. Following this examination the student brings his record, on which considerable data have been recorded, to another physician, who reviews all the facts, examines the reports that have come from parents and family physician, and checks any abnormal findings. In addition, he asks a few questions concerning past health, habits, interests and social relations that are designed to bring out attitudes and personality traits indicating present or future psychologic difficulties. Valuable

*From the Department of Health, Phillips Academy, Andover, Massachusetts. This study was aided by a grant from the Carnegie Corporation.

†School physician, Phillips Academy, Andover.

suggestions regarding such an appraisal can be obtained from a recent report of the Grant Study.⁵ After this conference the student receives a lung x-ray examination and any other x-ray or blood studies that are necessary. It is possible for two physicians to examine in a relatively thorough manner a large group of students within a short time, because many of the details of the examination are handled by trained assistants. It is found necessary to have a small number of students return for a more thorough investigation of some disorders: students requiring determinations of

Such a health examination as outlined above is time consuming and relatively expensive and should not be continued unless its results justify the expenditure. In Table 1 are listed findings made at the health examination of 910 boys.

The importance of the relation of weight to health can be overemphasized, but it is certainly advisable to follow the weight trend of those students who are obviously too thin or too fat. Assignment to either of these groups is made on the basis of general appearance and not on the deviation from standards given in height-weight-age

TABLE 1. Summary of Findings at the Health Examination of 910 Boys Ranging from 13 to 19 Years of Age.

FINDING	No. of SUBJECTS	Pct CENT	FINDING	No. of SUBJECTS	Pct CENT
Overweight	57	6.3	Duodenal ulcer	1	0.1
Underweight	54	5.9	Fibroma of preperitoneal tissues.....	1	0.1
Visual defects:			Hydrocele	2	0.2
Color vision deficient	48	5.3	Varicosities of abdomen.....	1	0.1
Vision with glasses, one or both eyes:			Undescended testes:		
20/30	54	5.9	One	4	0.4
20/40 or less	37	4.1	Both	1	0.1
Vision with no glasses, one or both eyes:			Posture defects:		
20/30	11	1.2	Severe	10	1.1
20/40 or less	17	1.9	Moderate	60	6.6
Hypermetropia with no glasses	70	7.7	Slight	270	29.6
Heterophoria	43	4.7	Recurrent shoulder dislocation.....	3	0.3
Dental defects (based on the examination of 354 boys):			Lower-back strain	4	0.4
Caries:			Muscular atrophy (after injury).....	3	0.3
Attention urgently needed.....	64	18.1	Flail ankle and knee (poliomyelitis).....	1	0.1
Attention needed	290	82.0	Cavus foot (poliomyelitis)	1	0.1
Orthodontia needed	44	12.4	Pott's disease	1	0.1
Tonsillectomy advised	21	2.3	Impacted bullet (femur)	1	0.1
Adenoidectomy advised	3	0.3	Cervical rib	1	0.1
Marked deviation of nasal septum.....	4	0.4	Hammer toe	3	0.3
Chronic severe allergic rhinitis.....	8	0.9	Unreduced elbow dislocation	1	0.1
Nose fracture with obstruction.....	1	0.1	Osteochondritis dissecans	2	0.2
Deformity of nasal septum and ear.....	1	0.1	Osteoma:		
Dislocation of nose (anterior quadrilateral car- tilage)	1	0.1	Femur	1	0.1
Perforation of eardrum	2	0.2	Tibia	1	0.1
Auditory defects:			Cyst of femur	3	0.3
Loss of 20 d.b. or more (high tones only) .	23	2.5	Epidermophytosis (moderate or severe).....	108	12.0
Loss of 20 d.b. or more (all tones).....	15	1.7	Eczema	4	0.4
Asthma	27	3.0	Pityriasis	2	0.2
Hay fever	91	10.0	Fibroma of posterior skull	1	0.1
History of intimate contact with tuberculosis...	21	2.3	Impetigo	1	0.1
Positive tuberculin test (0.01 mg. O. T.) (680 boys tested)	177	26.0	Acne:		
Definite history of rheumatic fever.....	15	1.6	Severe	65	7.1
Rheumatic heart disease	6	0.7	Mild	164	18.0
Congenital heart disease	2	0.2	Pigmented mole	2	0.2
Dextrocardia	2	0.2	Pilonidal sinus	20	2.2
Hyperextension:			Albuminuria:		
Severe	1	0.1	Transient	45	4.9
Slight	2	0.2	Orthostatic	27	2.9
Enlarged spleen:			Diabetes	2	0.2
Acute mononucleosis	1	0.1	Endocrine disorder	5	0.5
Etiology unknown	3	0.3	Personality disorder:		
Inguinal hernia	3	0.3	Moderate	21	2.3
			Slight	40	4.4
			Speech defect (stuttering):		
			Severe	5	0.5
			Moderate	10	1.1

the basal metabolic rate are asked to spend the night before the test at the infirmary; those with albuminuria are also asked to return so that urine specimens may be obtained before arising; those with orthopedic defects or disorders of the ear, nose or throat are re-examined as groups by visiting specialists; and those failing the vision tests are referred to a competent specialist for a more thorough examination.

RESULTS

Any medical procedure that becomes routine should be subjected occasionally to critical analysis.

tables; individual students because of their constitutional type and heredity and endocrine peculiarities vary tremendously in rate and type of development, and it seems to be most satisfactory to assess these persons by observation rather than by means of a chart. Those boys whose weight is considered abnormal are given a few suggestions and their weight is rechecked at appropriate intervals. Twelve per cent of the student body showed sufficient variations in weight so that their condition justified some further attention.

Boys with a deficiency in color perception (53 per cent of the group reported here) are told of the

presence of this condition and advised that it may exclude them from certain careers. The testing of visual acuity is most important: 1.9 per cent of the group were found to have no better than 20/40 vision in one or both eyes and yet did not have glasses; many of those who did have glasses had a corrected vision of only 20/40 or less, which in many cases could and should have been more adequately corrected. Many with hypermetropia or marked heterophoria were referred for a more thorough examination, and all those who had definite symptoms of eyestrain were referred to a specialist regardless of the findings at the time of the vision test.

The importance of including a careful survey of the teeth in any health examination needs little comment; that 18 per cent of a group of 354 students needed dental care urgently, and that many others had conditions requiring attention is further evidence of the need for paying special attention to the teeth of members of this age group regardless of their economic background. A more detailed report of these findings has been published elsewhere.⁶

Tonsillectomy is advised only either when obviously diseased tonsils are present or when moderately diseased tonsils are present and there is a history of frequent infection of the upper respiratory tract or rheumatic fever. In this group about 80 per cent had previously had a tonsillectomy. A small number of nasal deformities that should have been corrected were found; because of the age group, the number of septum operations advised was small.

The percentage of boys with severe asthma or hay fever was high. Many are urged to attempt to determine the value of desensitization procedures while the facilities of a school health service are available.

The testing of hearing, like that of vision, is particularly important among students. A list of boys with impaired hearing is sent to the school administration so that proper seating in classrooms can be provided; 1.7 per cent were found to have a considerable diminution of hearing.

The percentage of students having rheumatic heart disease was small; every effort is made to have these boys maintain an objective attitude toward their condition, and restrictions are lifted rather than imposed. All those who have had rheumatic fever are urged to report at the onset of any infection of the upper respiratory tract, and an attempt is made to have all those who have rheumatic heart disease take part in athletics just as do all other members of the student body.

Definite hypertension is unusual in this age group. Those unaccustomed to medical exam-

inations are often apprehensive, and may be found to have an abnormal blood pressure, but a persistent hypertension in a relaxed adolescent is certainly rare, and should be carefully investigated before one decides that it does not rest on an emotional basis.

Lung x-ray studies of members of this group revealed little disease but because they can be compared to subsequent films taken when disease is suspected, they may be of great value. Occasionally such findings as dextrocardia, cervical rib, small areas of pneumothorax or even extensive healed miliary tuberculosis were noted. Five members of a special survey group of 680 students were found to have the combination of a negative tuberculin test, pulmonary calcification and a positive skin reaction to coccidioidin.⁷ Twenty-six per cent of this group were found to be positive to 0.01 mg. of old tuberculin.

Examination of the abdomen and genitalia reveals only a small percentage of abnormalities, but the majority of these defects are important because they can and should be corrected. It is usually desirable to correct an inguinal hernia when it is found at this age, and testes that have not descended by the time secondary sex characteristics have developed are best treated by surgery; in younger boys hormone therapy is worthy of a trial. The finding of a benign fibroma in the abdomen is unusual, but again emphasizes what may be found when a reasonably careful examination is made.

A small number of orthopedic defects may be expected. Operative treatment for recurrent shoulder dislocation is advised when the dislocation occurs frequently or when the student expects to enter such an institution as the United States Naval Academy. Osteomas are only rarely seen; surgical removal is advised if the area is exposed to frequent trauma. Many of the more severe postural defects can be considerably benefited by proper corrective procedures.⁸

The importance of observing heavily pigmented moles and sometimes advising their removal is obvious. Acne is found more frequently in the more mature boys (about 88 per cent of the acne noted occurred in students who were classified as "mature"), and presents a real problem because of its psychologic implications, particularly for those whose adjustment is not satisfactory. The percentage of students who have a pilonidal sinus and who will subsequently develop a pilonidal abscess is problematical, but at present it is well for those who contemplate a career in aviation to know that such a condition is present.

When albuminuria is found in the first urine specimen, several other specimens are collected; if albumin persists, an orthostatic test is done. Of

those with persistent albuminuria, almost all will be found to be free of albumin when an early morning specimen, collected before arising, is examined. The insignificance of these findings has been commented on by Derow,⁹ but the condition continues to be a source of difficulty when application for life insurance or for admission to some institutions is made. The finding of glycosuria is very rare, but is certainly of sufficient importance so that this test should never be omitted. In this group 1 such case, previously unrecognized, was found.

A reasonable amount of experience with members of this age group and the utilization of a short series of well-selected questions enable one to detect the majority of those students who will have difficulty in adjusting to a boarding-school situation. It might be expected that few boys with personality disorders would seek admission to a secondary school of high standards where competition is keen. That about 6 per cent of this group appeared to lack the attributes necessary for a completely satisfactory adjustment indicates how desirable it is to attempt to estimate the subject's personality in any health examination.

Abnormalities in speech are easily detected, and are always worthy of attention. Stuttering obviously interferes with a student's scholastic efficiency and his proper adjustment; personal attention and adequate therapy can be expected to improve speech as well as to bolster the stutterer's morale.

The observations made at this examination do not permit a complete answer to the question of the student's fitness and do not give all the data by which one may answer his question, What condition am I in? It is desirable also to determine his ability to perform and to recover from brief exhausting work; that is, to test the efficiency of his cardiovascular and respiratory response to exercise. A simple but relatively accurate method of testing this type of dynamic physical fitness in boys has recently been described.¹⁰ A reasonable estimate may be obtained by utilizing the formula:

Duration of exercise (seconds) × 100

Fitness index = $\frac{\text{Sum of three pulse rates during the subsequent 4-minute rest period}}{\text{Duration of exercise (seconds) \times 100}}$

The exercise consists of stepping up to and down from a platform thirty times a minute; the usual duration is 4 minutes (240 seconds).

Table 2 lists the distribution of scores obtained when such a test is given, and indicates the wide range of dynamic physical fitness that obtains in such a group of boys, all of whom are apparently in good health. The desirability of obtaining this type of information before any student is given

an estimate of his condition is obvious; a crew captain may appear to be equally healthy and in equally good condition in June after three months of rowing and in September after two months of farming, but his dynamic fitness will be found to be very different at each of those times. So also the convalescent following the optimum per-

TABLE 2. Distribution of Physical Fitness Test Scores of 609 Boys Ranging in Age from 13 to 19 Years.

SCORE	NO. OF CASES	PER CENT
45	4	0.7
46-55	39	6.4
56-60	78	12.8
61-65	137	22.5
66-70	171	28.1
71-75	106	17.4
76-80	42	6.9
81-90	25	4.1
91-100	7	1.2
Total	609	

iod of recovery may appear to be just as healthy as ever, but his dynamic fitness will be low, and unless it is tested, one can hardly accurately estimate his fitness.

SUMMARY

A brief report of the findings made at the initial health examination of 910 boys in the thirteen-to-nineteen-year age group is given.

The number of important and correctable defects made at such an examination even when the subjects come from an economically privileged group indicates the desirability of this sort of examination for all adolescents.

The importance of including an estimate of the functional fitness of a subject as well as observations made on him at rest is suggested.

I am indebted to Drs. Henry Clifford, Earle Glendy, Norman Boyer, Mitchell Gratwick, Gustav Kaufmann, George Van Gorder, George Tobey, John C. Brown and Albert E. Sloane for their help and advice in connection with health examinations made during the last few years

THE NUTRITIONAL BACKGROUND OF PATIENTS WITH RHEUMATOID ARTHRITIS*

THEODORE B. BAYLES, M.D.,† HOPF RICHARDSON‡ AND FRANCIS C. HALL, M.D.§

BOSTON

FOR a number of years the medical profession has come to believe with increasing conviction that the health of normal people is determined considerably by the type of food they eat, and that this has been proved to be of specific importance in certain diseases. A revolution is taking place in the practice of medicine at the present time because of this added information regarding nutritional requirements, and with more knowledge of objective evidences of deficiency states, patients are being found in clinics and offices whose symptoms and signs point to these states as the cause of their difficulties. It is becoming a more routine procedure to look into the patient's dietary history, evaluating the absorption of his diet and estimating his dietary requirements.

It is natural that this knowledge should be applied to chronic diseases of unknown etiology, and as the result of such studies, rickets, scurvy, beriberi and pellagra are no longer considered infections but are ranked as deficiency states. Pernicious anemia is known to be due to lack of an absorbed food factor, and certain neurologic conditions are responding to vitamin therapy. Acute deficiency states have been more easily recognized than are chronic borderline ones, and the possibility that borderline deficiency over a long period of time can cause certain diseases of unknown etiology is being kept in mind. Recently, a thorough study of the vitamin B complex therapy and the life history of cirrhosis of the liver has suggested that this disease of unknown etiology may be added to the list of diseases due to an incomplete diet.¹

Students of arthritis have not been slow in considering the possibility that food deficiency plays a role in the types of this disease whose etiology is unknown, but at the present time there is no proof that a lack of any specific food is a causative factor. The present belief that rheumatoid arthritis is of infectious etiology has led many to conclude that the evidences of a food deficiency

state that are often found are secondary to the disease. Indeed, this type of study was prompted by finding the red, smooth tongue and skin changes of vitamin B complex deficiency in a large number of patients with rheumatoid arthritis. In any event, work²⁻⁴ has been done that shows that these patients commonly have a deficiency in certain dietary elements. An increasing number of physicians⁵ believe that this food deficiency state should be treated with a well rounded and adequate diet, and that when it is so treated the general health of the patient usually improves, and at times coincidentally the disease itself.

Investigations of the diet of patients with rheumatoid arthritis have been numerous and revealing.⁶⁻¹² On the whole, they have established the fact that many of the food elements important in a well balanced diet are lacking, but they have failed in most cases to evaluate the dietary history of the patient at the period in his life previous to the onset of disease. One of us (F. C. H.) attempted this some years ago, but he failed to pay sufficient attention to the patient's absorption of food or to his apparent requirements for certain food factors. In some patients severe dieting for obesity, chronic hyperperistalsis and burning the candle at both ends¹³ have been conspicuous in the histories just prior to the onset of the arthritis. A high carbohydrate diet with evidence in the stools of starch indigestion has been observed in patients with rheumatoid arthritis.¹² Our recent observations appeared to show that 37 per cent of 40 patients with this type of arthritis had borderline or deficient diets prior to the onset of the disease. With recognition of the presence of food deficiency states, further study of their nutritional histories seemed important.

The remarks by Castle and Minot¹³ on the dietary history in anemia are applicable in this study of the dietary antecedents of rheumatoid arthritis. They say

It is important to emphasize to the patient that it is a description of the diet antecedent to the present illness, by months or years that is wanted and that it is what the patient himself eats, not the family as a whole which is the essential information. A detailed statement of the food taken at each meal in the day together with a statement of the number of times per day, week or month that the articles mentioned are eaten and approximately what amounts as a time consuming but necessary feature of the diet history.

‡Volunteer research assistant, Robert Breck Brigham Hospital.
§Assistant physician, Robert Breck Brigham Hospital, and assistant physician, Boston City Hospital and instructor in medicine, Harvard Medical School.

This has been our purpose in this paper. We have tried to evaluate and measure accurately the dietary background of our patients for the year before onset of their rheumatoid arthritis.

MATERIAL AND METHODS

Fifty-three patients with rheumatoid arthritis on the charity wards of the Robert Breck Brigham Hospital were interviewed and questioned concerning their dietary history by the method outlined below. The diagnosis of rheumatoid arthritis was confirmed in each case by clinical, roentgenographic and laboratory studies. Of these histories, those of 22 patients were discarded because of language difficulty, obvious memory faults and failure of the history to withstand rigorous cross-checking, leaving 31 cases for dietary analysis. Some of these patients showed evidence of avitaminosis on the skin or tongue.

Since our attempt was being made to evaluate the dietary history for the year before the onset of rheumatoid arthritis, the first questions were designed to date and describe the first symptoms that related to the disease process. The actual date of onset was set arbitrarily as the time that the patient noticed actual joint swelling. This determination was more difficult in the patients with the Strümpell-Marie variety of rheumatoid arthritis than in the others, but here steady pain or stiffness of the back was used as the criterion.

When the history of the year before onset had been obtained, brief descriptions of infections, operations, pregnancies and hyperthyroid states were elicited. Since these conditions definitely increase the calorie and vitamin requirement, their temporal relation to the year before onset must be known. Further questioning revealed factors that probably affected the total calorie and vitamin requirement. These questions concerned occupation, past and present, working and sleeping hours, duration of hours of relaxation and the way in which these hours had been spent. It was thought that the patient's race, birthplace, residence, marital, social and economic states and eating habits—whether he ate at home or in restaurants alone or with his family—all had some bearing on the total intake and requirement. Simple questions designed to reveal conscious or unconscious emotional strain and fatigue were asked. The total requirement before onset was evaluated on the basis of the answers to the above questions and of the age, height and weight at the time under consideration. This figure was given a percentile value, using 100 as normal.

Absorption of the food substances in the diet was largely evaluated on the basis of number and

character of stools per day and the use of cathartics and enemas to produce increased peristalsis.

The dietary history began with the meals of childhood and ended with the food eaten on the day before admission. Special attention was given to information that might by similarity or contrast shed light on the dietary customs of the prearthritic years. The intake of a hypothetical day during this period and also that during one or more different periods were recorded. In every case the information about the most clearly remembered time was checked and amplified by a detailed account of the estimated quantities of each of the fifty foods and beverages on a selected list that might be consumed in an average week. Special diets, prescribed or self-imposed, were listed and sometimes computed. The differences and similarities between the various periods were constantly stressed.

It was assumed that one seventh of an average week's intake should approximate, quantitatively and qualitatively, the corresponding typical day's intake. When this did not occur, the patient's accuracy was doubted. (In order to obtain a more logical picture the information about corresponding days and weeks was sought in separate interviews.) The history was considered inaccurate if the results of the computation of the diet seemed to disagree with the impression given by the patient, or if any of the figures for the two periods or for any period were too bizarre to be probable under the given circumstances. This rigorous cross-checking eliminated the majority of histories that were discarded.

The patient was asked to describe his appetite at different times by a single adjective. Brief inquiries into symptoms of allergy and indigestion were made. Prominent likes and dislikes of food were noted. Spontaneous comments on any of these topics were encouraged, as were comparisons of the patient's food habits with those of other people. Indications of strong feelings or parental attitudes on questions of diet were indirectly sought and noted.

The relative quantities of food contained in home-cooked meals were described by the patients in terms of hospital-diet servings, whereas restaurants were assumed to provide generally accepted averages. When several varieties of food were grouped under a single heading, such as "vegetable other than potato" or "cooked fruits," the available figures for those commonly used were averaged. Many similar compromises were made in estimating the food values of typical days, thus decreasing the distortion possible from the chance inclusion of some single high-vitamin food.

The composition and caloric content of the diets were estimated from charts giving data on the edible portion of uncooked food.¹⁴ The figures used for calcium, iron, thiamine, riboflavin and vitamin A were also estimated from values for un-

thrictic history seem to demand consideration. Such factors as trauma, infection, exposure, operations, increased activity, loss of weight, loss of appetite and increased nervousness did not appear to precede the arthritis in more than a small percentage

*These figures show the nutritive values per nutrition requirement unit—equivalent to the daily allowance for a moderately active man weighing 154 pounds (70 kg)—for diets of families at different 1936 price levels per person per week. These averages refer to food brought into the kitchen and take no account of the edible food waste or nutritive losses resulting from cooking.¹⁵

†These figures are taken from a table¹⁶ that presents a tentative goal toward which to aim in planning good diets for normal people at different levels of age and physical activity. The values refer to the amount of each factor to be eaten.

cooked foods, but deductions of 30 and 35 per cent, respectively, were made to allow for the thiamine lost in cooking vegetables and meats.¹⁵ The vitamin C figures were taken from a table that included analyses of foods subjected to various processes, such as storage, cooking and reheating.¹⁶ Other recognized sources were consulted in the few cases in which these did not yield the required information.

RESULTS

Table 1 presents the quantitative data obtained in this study. Certain features of the general ar-

thritis history seem to demand consideration. Such factors as trauma, infection, exposure, operations, increased activity, loss of weight, loss of appetite and increased nervousness did not appear to precede the arthritis in more than a small percentage of cases. On the other hand, 12 patients gave histories of skeletal or muscular pain that had persisted or recurred for one month to several years before the first joint swelling considered the actual onset of arthritis. Nine patients described changes in physical vigor that preceded the arthritis by one month to three years. Six patients thought there had been a one-year or two-year period of increased emotional strain before the onset. In 10 cases, changes in home, school or working conditions seemed to bear a temporal relation to these variously diagnosed symptoms. Of the 5 patients who had pregnancies within

three years before the onset of arthritis, 3 failed to recover their previously good health. Although 8 patients said that they had been constipated for years or always, none thought that this had increased in the year before onset. It is interesting that none of this group complained of diarrhea—but they did use cathartics freely.

In evaluating the factors in the diet, we have compared our findings with three sets of standards: first, when possible, with actual requirements as mentioned by various authors to be quoted; second, with the average American diet in North Atlantic cities¹⁷; and third, with the recommendations of the National Research Council for an optimal diet.¹⁸ The results, evaluated by these three standards, are as follows:

Calories. The criterion for energy requirement was met by maintenance of normal body weight. The 4 patients who lost weight were considered to have had too few calories. Three patients gained weight. The average intake was 2712 calories, with the wide range of 1378 to 3758 calories. In their study of present-day diets in the United States, Stiebling and Coons¹⁷ found average daily caloric intakes of 2530 and 3320 at different price levels among families in cities of the North Atlantic states.

Protein. The average protein requirement of a 70-kilogram man has been stated to be 44.4 gm. daily, and it is customary to allow from 10 to 15 per cent of the total calories for protein.¹⁵ The average daily protein intake in our series was 84 gm., and single diets contained from 51 to 163 gm., accounting for 10 to 17 per cent of the total calories. There was no intake below 44.4 gm. Four females had questionably low protein intakes of less than 55 gm., but the general average was higher than those of 64 and 88 gm. found by Stiebling and Coons.¹⁷ Nine females and 1 male had less than the absolute quantity recommended by the National Research Council,¹⁸ but none of these were inferior to this recommendation in their ratio of protein to total calories.

Carbohydrate. A daily average of 286 gm. of carbohydrate, with a range of 151 to 476 gm., or 34 to 66 per cent of the total calories, was found in the diets. In only 6 of these did carbohydrates appear to have accounted for more than 50 per cent of the calories. This was an unexpected finding, since it is generally believed that patients with rheumatoid arthritis use a high-carbohydrate diet.

Fats. The average daily fat intake was 112 gm., with a range of 46 to 216 gm., or 24 to 53 per cent of the total calories. This was not very different from the average in the United States,

where it is generally accepted that about one third of the food calories are taken in the form of fat.¹⁵ If anything, the intake was high in this respect, since 16 patients took over 40 per cent of their calories in the form of fat.

Iron. The estimated iron need of the normal man or woman is 8 mg. daily.¹⁵ Our patients had an average of 15 mg. (females 13.4 mg., males 17.5 mg.), with a range of 8 to 26 mg. Three women, however, took less than 10 mg. daily. One of these was sixteen years old and obviously should have had more iron. Stiebling and Coons¹⁷ found average iron intakes of 11.3 and 15.4 mg. for two economic groups. Although all our patients apparently met their actual requirements, 7 women had less than the National Research Council's¹⁸ recommendation for their age group.

Calcium. The normal requirement for adults is probably a little over one hundredth of the protein requirement, or approximately 0.45 gm. daily, whereas the present standard of adequacy for those who have not reached full skeletal growth is 1.0 gm.¹⁵ Our patients had diets containing 0.27 to 1.60 gm., with an average of 0.7 gm. Twelve had less than one hundredth as much calcium as their protein requirement. An eighteen-year-old girl had less than one third of the standard amount thought needed during growth. Three other girls under twenty years of age had distinctly less than 1 gm. Three men with rheumatoid arthritis had 50 per cent of their estimated requirement, and 1 had only 36 per cent. Three men with Strümpell-Marie arthritis had less than their requirement, 1 of them by over 50 per cent. However, this evidence of low calcium intake is also found in other American diets. Stiebling and Coons¹⁷ found averages of 0.44 and 0.65 gm. in their two groups, and Sherman¹⁵ found a range of 0.24 to 1.87 gm., with an average of 0.73 gm., in the one hundred and fifty families included in his study. The recommendations of the National Research Council¹⁸ were met by only 4 females and 2 males.

Vitamin A. Computation of the vitamin A value gave results ranging from 2715 to 9193 international units, or much higher if vitamin supplements were included. Although vitamin A content cannot be judged with any precision, probably no patient had as little as 1750 international units, which is the lowest requirement figure for a person weighing 70 kilograms.¹⁵ Stiebling and Coons¹⁷ suggested that the 2100 and 3400 international units of vitamin A value given in the diets studied by them might be too low.¹⁷ Although the average of the diets in our group (omitting supplements) was around 6000

international units, 7 females and 3 males had less than the amounts in the National Research Council's¹⁸ table.*

Thiamine. The thiamine requirement may be stated in terms of the ratio between micrograms of thiamine and non-fat calories.¹⁵ The average ratio necessary to protect against beriberi is 0.3.¹⁹ The thiamine nonfat calorie ratio in our patients averaged 0.8, ranging from 0.4 to 1.5. The average thiamine intake was 1.0 mg. and the range was from 0.4 to 2.4 mg. daily. Stiebling and Coons¹⁷ found averages of 340 and 500 international units or 1.0 and 1.5 mg. (with no allowance for cooking losses) in the diets they studied. The National Research Council¹⁸ recommends more thiamine than was found in the diets of our patients with the exception of 4 females and 2 males with rheumatoid arthritis; since, however, the allowances for thiamine are proportional to total calories, quantitative comparisons with diets high in fat may be misleading.

Riboflavin. The minimum daily riboflavin requirement proposed for adults is 1.0 mg.¹⁵ Our patients had from 0.9 to 2.7 mg., with an average of 1.7 mg. Eight patients, 6 of them females, had between 0.9 and 1.3 mg. Stiebling and Coons¹⁷ found averages of 470 and 700 international units (1.2 and 1.8 mg.). Although the average of riboflavin in our patients' diets was apparently as good as or better than that in the average American diet, only 10 patients met the standards of the National Research Council.¹⁸ Seven out of 8 male patients with rheumatoid arthritis and 3 males with Strümpell-Marie arthritis had considerably less than this recommendation and it was met by only 7 females.

Vitamin C. The vitamin C requirement of adults is stated to be 1.0 mg. per 100 total food calories, or about 25 mg. daily.¹⁵ The intake of patients with rheumatoid arthritis averaged 62 mg. and ranged from 8 to 161 mg., or from slightly more than one half to ten times the requirement in relation to the number of total calories. Eight patients had intakes of less than 25 mg. and 8 had between 25 and 50 mg. in their daily diet. In definite contrast were several high vitamin C intakes (114, 120, 138, 152 and 161 mg.). Stiebling and Coons,¹⁷ calculating the ascorbic acid content of the uncooked foods of families in North Atlantic cities, found averages of 41 and 70 mg. per person. Again, as compared to the National Research Council's¹⁸

recommendations, 11 females and 3 males with rheumatoid arthritis were deficient in vitamin C. None of the patients with Strümpell-Marie arthritis had as much as the allowance for their ages.

COMMENT

Studies of the diet and nutritional status of patients with rheumatoid arthritis have revealed many deficiencies in intake and a lack of vital foodstuffs that can be observed in patients or measured in the chemical laboratory.²⁻¹² The present survey indicates that the dietary history of these patients before onset is not grossly different from that of a cross section of employed families in the North Atlantic states.¹⁷ However, over two thirds of the patients fell short of the National Research Council's¹⁸ recommendation for calcium, thiamine and riboflavin; about half had an inadequate intake of vitamin C, and a small number were deficient in protein, iron or vitamin A or its precursors by the standards set by this council.

These facts seem to be of great significance until it is realized that in terms of actual requirement only a few patients gave a history of an abnormal foodstuff intake that would lead to obvious clinical deficiency states, and that then only calcium and vitamin C were involved. The rather high incidence of signs, symptoms and laboratory findings of food-deficiency states observed in groups of patients such as these should be ascribed to a deficiency resulting during the course of the disease or to an essentially normal dietary background that has been made relatively insufficient by abnormal requirement caused by such factors as increased work, worry and chronic fatigue.

The analysis of this series indicates that the greatest tendency toward deficiency lay in the requirement background of the patients rather than in the actual food consumed. All but 7 had unusual expenditures of nervous or physical energy prior to the onset of disease, and this produced the same result that faulty food intake would have produced.

The etiologic factor or factors involved in rheumatoid arthritis are still to be elucidated, but from this study it seems apparent that if a food factor contributes to the onset of this disease process, its lack is brought about by an increased requirement rather than by a deficiency in intake. The results of the study do not invalidate the evidence for definite food deficiency in individual patients with rheumatoid arthritis; they only indicate that the dietary background of the patients studied is within average limits. Until patients can be studied before onset of the disease it must

*A note on this table adds that requirements may be less if vitamin A is provided as such and if it is chiefly provided as the pro-vitamin carotene.

be assumed that the food-deficiency state is probably secondary to the disease.

SUMMARY AND CONCLUSIONS

The dietary history of 31 patients with rheumatoid arthritis was reviewed for the year before the definite onset of their disease process. This history appeared to show that the food intake was essentially the same as that of a cross section of families in the North Atlantic states. The intake of calories, protein, fat, carbohydrates, vitamin A and its precursors, thiamine, riboflavin, vitamin C, calcium and iron was studied.

If a food-factor deficiency contributes to the onset of rheumatoid arthritis this study suggests that it must be caused by an increased total requirement of the patient rather than in a deficiency in his average diet. In single cases a deficient diet may be found to have been present prior to the onset of the disease. It should always be looked for and corrected when found. The very frequency of evidences of deficiency states during active rheumatoid arthritis suggests that this disease increases the food requirements, especially of the vitamin B complex.

MEDICAL PROGRESS

ADVANCES IN MALARIA RESEARCH (Concluded)

QUENTIN M. GEIMAN, PH.D.*

BOSTON

IMMUNITY

SIGNIFICANT recent advances have been added to the knowledge of immunity in malaria. Immunity in this infection has been little understood, and even questioned, but the results achieved within recent years offer encouragement and methods of approach for an eventual solution of unsolved problems. An understanding of the newer available knowledge is of particular importance to the clinician and epidemiologist who are called on to treat and study the occurrence, spread and control of this disease.

Extensive studies with human malaria, particularly induced malaria, have definitely proved that patients acquire immunity during the course of an infection. James in England, Ciuca in Rumania and Boyd and his collaborators in America

and others have helped to explain race susceptibility to malaria, and the development of immunity not to a species of *Plasmodium* but to strains or races of each species. The immunity that is acquired is highly effective against reinfection with the homologous strain, but fails to protect against heterologous strains and species of parasites.

This discovery of different strains within a species helps to explain the resistance or tolerance of a given population to the local strains, the length of time it takes the effective immunity to develop susceptibility to foreign strains, the variable clinical activity observed for different strains of the same species and finally the variable response to antimalarial drugs. James and Ciuca¹⁷ cite the work of Korteveg, who compared two strains of *Plasmodium vivax*, one from Holland and the other from Madagascar. Infection with the Holland strain remained latent in 38 per cent of cases; there was an average incubation period of twenty-one days, giving 19 per cent with quo-

The articles in the medical-progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5.00).

*Instructor in comparative pathology and tropical medicine, Harvard Medical School and Harvard School of Public Health.

tidian paroxysm, 8 per cent with fever above 106.4° F., 10 per cent with spontaneous recovery and 10 per cent with relapses and a high resistance to neosalvarsan. The Madagascar strain was a much more virulent one, with 7 per cent latency, an incubation period of twelve days, 80 per cent with a quotidian paroxysm, 30 per cent with fever over 106.4° F., no spontaneous recoveries, a relapse rate of 80 per cent and high susceptibility to neosalvarsan. DeBuck (also cited by James and Ciucu) found that the Holland strain produced an average number of 13 merozoites (range 8 to 20) while the mean in the Madagascar strain was 18 (range 8 to 32). Furthermore, immunity acquired against the Madagascar strain did not protect against the Holland strain.

James, Nicol and Shute⁷⁰ compared strains of *P. falciparum* from Rome and India. Clinically, the strain from Rome produced severe disease and even several cases of blackwater fever, in contrast to mild attacks from the Indian strain. *Anopheles maculipennis* could be infected with the Italian but not with the Indian strain. Furthermore, patients recovering from attacks caused by the Indian strain were susceptible when reinoculated with the Roman strain. Boyd and his collaborators⁸⁰⁻⁸² conducted similar studies with American strains of *P. vivax* and *P. falciparum*. They found clinical and immunologic differences between strains, and also differences in their ability to infect anopheline vectors.

Homologous immunity develops to strains of *P. malariae*, but variations between strains of *P. ovale* are not yet clear. The only case of cross or heterologous immunity between species infective for human beings exists for *P. vivax* in patients recovering from infections with the simian parasite *P. knowlesi*,⁷⁷ but Milam and Kusch⁸³ failed to demonstrate the reverse.

Two approaches have been used to elaborate the mechanism involved in natural and acquired immunity. Cellular reactions to various types of malaria have been carefully studied, and standard immunologic methods have been utilized in investigating humoral response to infection.

Observations on phagocytosis of parasitized red cells, extracorporeal parasites and pigment in malaria began with the early, thorough and brilliant observations of Laveran and Golgi, and represent the most consistent findings in the pathological literature of this disease. The extensive work of Cannon and Taliaferro,⁸⁴ Taliaferro and Cannon⁸⁵ and Taliaferro and Mulligan⁸⁶ has clarified experimentally the sequence of events in avian and simian malaria.

Defense against the infection depends on the response of the lymphoid-macrophage system. The process of phagocytosis takes place primarily in the spleen, with decreasing activity in the liver and bone marrow. Natural immunity to the infection is evidenced during the early days of the infection by a relatively small amount of phagocytosis. During and after the crisis, the phagocytic activity is greatly increased and is associated with proliferation of macrophages. This initial response requires time for mobilization in nonimmune animals, but the response after superinfection is very rapid in animals with acquired immunity. The proliferation of lymphoid-macrophage tissue in the spleen offers a basis for splenomegaly or the progressive increase in size of this organ during the course of the disease. This cellular defense is active only against the strain or race of parasite that caused the infection. With each new infection, the same sequence of events appears to be necessary in order to build up cellular defense.

The greater susceptibility of children to malaria indicates either that more time is necessary to acquire effective immunity or that the defense mechanism in children is not so efficient as that in adults. Many workers have shown that the incidence of clinical malaria begins to decline at two to five years and drops rapidly to sixteen years and over, even though high parasite and splenic rates persist. Apparently this type of immunity is immunity against clinical symptoms, not parasites, and depends on the persistence of parasites in the subject. In fact, the terms "premunition"⁸⁷⁻⁸⁹ and "infection immunity"⁹⁰ were coined to differentiate the type of immunity in malaria from that in which the infection has subsided and the causative organism is no longer present. There is evidence, however, that acquired immunity may persist for three and a half to five years after the initial attack, without the persistence of parasites in the tissues. These cases were adequately controlled by subinoculating normal persons with large quantities of blood. On the other hand, malaria, particularly quartan malaria, may remain latent for twenty years or more and infect a normal person when blood is given for transfusion.^{91, 92}

Early attempts were made to demonstrate the therapeutic value of immune serum in malaria.⁹³⁻⁹⁵ The qualitative and quantitative demonstration of passive immunity by Coggeshall and Kumm⁹⁰ showed conclusively that protective antibodies are present in the circulating blood of monkeys with chronic malaria. Later the more potent effect of hyperimmune serum produced by superinfection was shown.⁹⁷

As previously mentioned, complement-fixing antibodies^{22, 26} and agglutinins³⁰ were demonstrat-

ed in monkey malaria, *P. knowlesi* being used as an antigen in both cases. The complement-fixation reaction became positive promptly after an acute attack and then dropped slowly, to rise again after a relapse. The titers varied from monkey to monkey, but with no relation to the parasite index. Serums giving high titers did not always confer high protection in the experiments on passive immunity. The reaction was later used to test serums from cases of induced human malaria with *P. knowlesi*, *P. vivax* and *P. falciparum*, and from naturally acquired tertian and malignant tertian malaria. The interesting and important results of this work showed that the reaction was group specific and not species specific and, furthermore, that the reaction with *P. knowlesi* as an antigen had a practical application to the diagnosis of human malaria.

The work of Dulaney and Stratman-Thomas²⁷ and Dulaney, Stratman-Thomas and Warri²⁹ on serums from naturally acquired and induced human malaria, and that of Kligler and Yoeli²⁸ on serums from malaria in a hyperendemic area, demonstrate that the test is specific and reliable and of practical value. Technical difficulties, however, make the reaction a supplementary test to the simpler and easier routine blood examinations. Another interesting discovery was the failure of pre-existing syphilis to interfere with the specificity of the reaction. When the syphilitic reagin is absorbed out of serums from a syphilitic and malarious patient, the serum reacts as before for complement-fixing antibodies. The reverse is not true, for it is well known that serums from patients with malaria give false-positive Wassermann and Kahn reactions.⁹⁸ These reactions exist for variable times during and after clinical malaria, showing that malaria must be ruled out in a patient from an endemic malarious area before he is given treatment for syphilis.

The agglutination reaction in simian malaria was found to be species specific by Eaton. Because of difficulties in obtaining suitable human antigen, the test is of little practical value for diagnostic purposes. An interesting finding that may have more bearing on the slow antibody response was the failure to obtain agglutination of red cells containing immature parasites. Perhaps the limited time that the mature intracorporeal parasites and extracorporeal merozoites from segmentation can act as antigens explains the relatively slow development of immunity.

The highly specific agglutination reaction of sporozoites when the infected salivary glands of mosquitoes are dissected in homologous immune serum is a more recent development that may be of far-reaching importance. This phenomenon

was originally observed in 1900 by Stephen and Christophers cited by Mulligan and Russell.³¹ Mulligan, Russell and Mohan,³² using *P. gallinaceum* of chicken or fowl malaria, obtained agglutination in dilutions ranging from 1:1000 to 1:65,000. When wild infected mosquitoes were dissected in human serums from chronic cases of malaria in the same locality, sporozoites agglutinated in dilutions of 1:4000 and 1:8000. In these same human immune serums, sporozoites of *P. gallinaceum* agglutinated only in dilutions of 1:128. Thus, agglutination of sporozoites appears to be highly specific and sensitive to humoral antibodies. Whether or not the procedure can be used for the diagnosis of human malaria will depend on the development of methods for rearing and maintaining a constant supply of heavily infected mosquitoes.

Russell, Mulligan and Mohan⁹⁹ tested the agglutinogenic effect of sporozoites of *P. gallinaceum* inactivated by ultraviolet light. A higher agglutinating titer was obtained in this way than by blood inoculation of the homologous plasmodium. An agglutinating titer of 1:32,000 or higher lowered the mortality rate from 51.4 to 7.7 per cent. When fowl immunized against sporozoites were inoculated with homologous trophozoites, no protection was detected.¹⁰⁰ In a later series of experiments by Russell and Mohan,¹⁰¹ vaccinations with inactivated sporozoites, injections of homologous immune serums and combinations of both vaccine and serum gave mortality rates of 21.1 per cent, 16.7 per cent and 7.3 per cent, respectively. The incubation time was not affected, but the intensity of infection was lowered. Since the greatest prophylactic effect was obtained in the third series, these authors believe that there is a combined action of humoral and cellular mechanisms in defense against malaria.

A successful precipitin test has been developed,³³ with use of an extract of infected placenta for the antigen. The scarcity of such antigenic material has prevented the adoption of the procedure. Stratman-Thomas and Dulaney³⁰ were unable to get positive results with antigens made from human blood. Dulaney and House,³⁴ however, have been able to get precipitative reactions in human malaria with an antigen of *P. knowlesi* using the collodion-agglutination technic of Cannon and Marshall³⁵ and the collodion-fixation procedure of Goodner.³⁶ Since these methods were found by their original authors to be highly sensitive when compared to the standard precipitin reaction, they appear to be the methods of choice also for human malaria.

When one attempts to correlate the above findings, it is pertinent to recall the provisional theory that Welch¹⁰² proposed in 1897 to explain what

he termed natural resistance to the malarial parasite—a theory similar to that accepted regarding resistance to bacteria. He postulated that . . .

. . . the parasites are destroyed by parasitocidal substances both in the plasma and within leukocytes and other phagocytic cells. The substances injurious to the parasites are in the last analysis furnished to the plasma by the cells and are in a more concentrated or potent form within the cells than in the fluids. This theory assigns to the phagocytes a higher role than that of mere scavengers. They are endowed in especial degree with the power of destroying the parasites, but this power is shared by the plasma.

Smith¹⁰³ also suggested that malarial immunity may reside both in the blood and in the host cells themselves.

The theory of Welch and the suggestion of Smith now appear to be correct, for available information suggests that cellular and humoral immunity do not work independently, but combine to aid the host in defense. The experimental evidence supports this view. The results of Russell and Mohan¹⁰¹ have already been cited, but the work of Mulligan, Sommerville and Swaminath¹⁰⁴ also confirms this opinion. In simian malaria, immune serum failed to affect the course of the disease in splenectomized monkeys. Furthermore, the enhanced value of immune serum in treating infections with *P. knowlesi* depended on the degree of stimulation of the lymphoid-macrophage system caused by the previous injection of another species of parasite (*P. cynomolgi*). The determination of more definite and precise relations between cellular and humoral mechanisms in defense against malaria will have to await the results of correlated quantitative studies on the cellular response and circulating antibodies.

In the foregoing account, the evidence for cellular defense and protective antibodies in malaria has been briefly reviewed. The studies demonstrate the slow but gradual increase in the development of acquired immunity. When the course of the infection has been interrupted by immediate treatment, the formation of antibodies is prevented and hence no immunity is acquired. One can readily see that here is the basis for the frequent observation in a native population that a "seasoning process" to malarial paroxysms is necessary before beginning treatment. Thus, the experimental results of recent years give credence to the above observation learned by experience in malarious areas.

Assuming the variation of specific antigenicity and host response under extreme conditions of climate and malnutrition, the level of immunity or activation of the lymphoid-macrophage system

and production of protective antibodies is entirely dependent on the intensity and duration of the infection. Short-lived infections produce little or no immunity. In long-standing chronic infections, a high grade of immunity is acquired. Observations on the potency of immune serum, the development of humoral antibodies and cellular defense support the statements.

Thus, Sinton,¹⁰⁵ who has compared his results of treatment on the development of immunity in simian malaria (*P. knowlesi*) with observations by other workers on the treatment of human malaria, points out that circumstances should determine the aim of the practitioner in the treatment of malaria. If there is little chance of reinfection, attempts should be made to effect a radical cure with suitable antimalarial drugs. If radical cure is not achieved and a relapse develops at a later date, the patient should undergo series of paroxysms before treatment is resumed. If such a procedure is to be carried out successfully and without fatalities in patients relapsing with *P. falciparum*, the blood must be examined daily to follow the parasite density and treatment must be resumed if the concentration of parasites approaches a dangerous level (100,000 per cubic millimeter).¹⁰⁶ If patients appearing for treatment are constantly exposed to reinfection, radical cure should not be attempted but rather a rapid cure of clinical symptoms only. There is ample evidence of the higher morbidity and mortality rates in endemic and hyperendemic areas where radical cures rather than clinical ones are attempted. The persistence of low-grade infections helps to maintain and even build up effective immunity against the local strains of parasites. The loss of immunity in a malarious area leads eventually to outbreaks of epidemic malaria.

TREATMENT

Advances in the treatment of malaria leave much to be hoped for and accomplished, since the ideal drug for malarial therapy has not been found. Despite the widespread incidence of malaria, there is no general agreement about the methods of treatment. Actually this situation is what one might expect when one considers the great variety of parasitic strains, the wide difference between benign tertian and malignant tertian malaria and in addition the effects of race susceptibility, acquired immunity, malnutrition and many other factors that make up the state of health of the human host in his environment.

Three antimalarial drugs have been tested and used successfully: the cinchona alkaloids, of which quinine is the best known, and two synthetic drugs, atabrine and plasmochin. Atabrine is the

only substitute for quinine, because plasmochin is useful only as an effective drug for the specific destruction of the gametocytes or sexual stages of malignant tertian malaria that lead to the infection of anopheline mosquitoes and transmission of the disease.

The loss to this country of the Netherlands East Indies has cut off the source of 90 per cent of the supply of quinine.¹⁰⁷ This fact has caused an emergency situation in view of the great need for antimalarial drugs for prophylaxis and treatment of great numbers of troops operating in endemic malarious areas. Thus, the War Production Board has frozen and restricted the use of all stocks of quinine and other cinchona alkaloids. Furthermore, the National Research Council undertook to investigate the available supply, use and standardization of cinchona bark from South America for the production of totaquine, a compound of cinchona alkaloids (quinine, quinidine, cinchonine and cinchonidine). Fortunately this compound was investigated by the League of Nations¹⁰⁸ some years ago and the results obtained from it were found to be more or less equivalent to those obtained by the use of quinine alone. Totaquine has now been recognized by the *Pharmacopoeia of the United States* and the definition appears in a supplement to the twelfth edition.

Until supplies of quinine and totaquine have been built up and made available, necessity forces the use of atabrine. The production of this synthetic drug has been greatly increased by the War Production Board, and presumably adequate supplies for all needs are available.

Here again, the League of Nations¹⁰⁹ conducted experiments on the relative prophylactic and therapeutic value of atabrine versus quinine. Patients with induced and naturally acquired malaria were used, and experiments to eradicate malaria were conducted. The experiments involved a total of 12,288 persons in five areas—Algeria, Italy (Sardinia), Federated Malay States, Rumania and the U.S.S.R. The studies of Clark et al.¹¹⁰ in Panama and of other workers in Africa and in India have also aided in assessing the therapeutic and prophylactic value of atabrine.

Atabrine is an effective prophylactic drug (except in hyperendemic areas) when two tablets (0.1 gm. or 1½ gr. each) are taken on two successive days each week. The recommendation by the British and American armies advises a two-day or three-day interval between days of medication.¹¹¹ A daily prophylactic dose of 0.06 gm. was the method used by the Germans in the Balkan campaign of the present war.¹¹² Daily prophylactic doses not exceeding 0.1 gm. are considered advisable for troops in hyperendemic areas where malignant tertian malaria is prevalent.¹¹³ The ac-

cepted dosage for clinical malaria is one tablet (0.1 gm.) three times a day for seven days. Since the drug is accumulative, an interval of seven to ten days should elapse before another course is given. In the treatment of acute malignant tertian malaria, Bryant¹¹⁴ used two to three times the accepted dosage profitably, giving sweet hot tea simultaneously to lessen the occurrence of toxic symptoms. For cases of acute malaria in adults, where rapid absorption is required to control symptoms, atabrine musonate* can be injected slowly intramuscularly (0.3 gm. in 10 cc. of distilled water divided into three daily doses) or intravenously (0.3 gm. in 20 cc. of a 10 per cent solution of glucose divided into three daily doses). There is no agreement about the route of choice.

Slight toxic effects—gastrointestinal disturbances, nervous and mental symptoms and yellow pigmentation of the skin—occur in a certain percentage of patients treated with atabrine, but these untoward effects are usually temporary and the yellow pigmentation is not the result of liver damage.¹⁰⁹ Toxic effects are more pronounced in children, and for this reason quinine is still the drug of choice in treating children up to five years of age. Junge¹¹⁵ has made some interesting observations in a report on the continuous use of atabrine for prophylaxis over a period of seven years. Twenty Europeans in Liberia were involved, and each subject took 143 gm. of atabrine in the elapsed time without injury to general health, even though yellow pigmentation was constant. The original daily dose of 0.1 gm. was cut to 0.05 gm., and no malaria developed in three and a half years. When the dosage was cut to 0.03 gm. daily, 16 persons came down with quartan or malignant tertian malaria, demonstrating that the effective prophylactic dosage was not less than 0.05 gm. daily.

The tendency of patients with malaria to relapse after treatment with quinine is characteristic. In a series of controlled experiments by various workers, the relapse rate after treatment with atabrine is slightly less than that after quinine.¹⁰⁹ There are still relapses, however, and so long as relapses occur after the use of any drug, transmission can take place if the anopheline vectors gain access to a blood meal containing gametocytes of the plasmodium. Furthermore, the following fact must be emphasized: atabrine has no effect on the gametocytes of *P. falciparum*, and patients with this type of malaria must be treated also with plasmochin.

Plasmochin has no value for the treatment of clinical malaria, according to various authors.

*In this country, atabrine dihydrochloride is usually employed. The intramuscular dose is 0.1 gm., dissolved in 3.5 cc. of distilled water, and the intravenous dose, 0.1 gm., dissolved in 10 cc. of distilled water, each given three times daily.

This drug has a definite effect on the gametocytes of the three species of malarial parasite, being especially effective against gametocytes or the "crescents" of *P. falciparum*. For this reason a course of the drug is given after quinine or atabrine to prevent transmission of malignant tertian malaria. The correct dose is 0.01 gm. (3/20 gr.) three times daily after meals for five days. The drug is highly toxic, and only 0.02 gm. per day should be given to a debilitated patient. Also, the drug should never be given at the same time as atabrine, because the two enhance the toxic symptoms of one another. This is not true, however, for quinine and atabrine, since Hill and Howie¹¹⁰ report the successful simultaneous use of quinine (10 gr. three times a day) and atabrine (1½ gr.) three times a day for seven days in treating 200 cases of malignant tertian malaria.

The combined or QAP treatment, used in India by Amy and Boyd¹¹⁷ and later by the British Army, has been endorsed by the Subcommittee on Tropical Diseases of the National Research Council.¹⁶⁷ This procedure is now considered the treatment of choice for acute malaria. Owing to its more rapid action in controlling the pyrexia and multiplication of parasites, quinine sulfate or totaquine (0.64 gm. or 10 gr.) is given three times a day for two or three days. Atabrine (0.1 gm. or 1½ gr.) is then given three times a day after meals for five days. After two days' rest from medication, plasmochin (0.01 gm. or 3/20 gr.) is given three times a day after meals for five days. For less serious cases, atabrine-and-plasmochin or quinine-and-plasmochin combinations are satisfactory.

Blackwater fever or hemoglobinuric fever, a disease that is connected with attacks of malaria or continuous malarial infection with *P. falciparum*, has not been considered above because of limited space. The treatment in brief consists of symptomatic relief, cessation in most cases of treatment with antimalarial drugs and administration of an alkali to render the urine alkaline within twenty-four hours after onset¹¹⁹; in acute cases, blood transfusions are decidedly helpful. No specific drugs for this disease are known. For a full account of blackwater fever and its treatment, the reader is referred to textbooks on tropical medicine.

Physicians or medical officers treating their first cases of malaria should be aware of the possibility of relapse after any known method of treatment and follow the patient accordingly. Furthermore, malaria may assume a great variety of clinical manifestations that are not commonly described in the typical textbook discussion. The same is true to some extent of response to treatment. Consequently, malaria in one of its many forms should be expected in a patient returning from an en-

demic malarious area until a thorough, accurate blood diagnosis establishes the absence of plasmodia. If patients with malaria are refractory to the usual methods of treatment, further information should be sought from more complete accounts on the therapeutics of malaria.^{9-11, 118-120}

The persistence of a low relapse rate in malaria after all known methods of treatment, and the failure of prophylaxis with quinine or atabrine to kill the infective sporozoites and prevent infection, have provided the stimuli for continued efforts to find new and more effective drugs. In fact, the war and its disastrous effect on our source of quinine has made studies in the chemotherapy of malaria one of the foremost and urgent fields of research. The approach to this pressing problem has been varied, and a colossal amount of work in preparing and testing new compounds has been and is being done.

Effort has been concentrated to a large extent on the quinoline and acridine compounds because of the antimalarial activity of the cinchona alkaloids, atabrine and plasmochin. The compounds prepared and tried are numerous. A thorough review of this subject and the general subject of chemotherapy of malaria has been compiled by Williams.¹²¹ The sulfonamides, including the well-known compounds and lesser-known derivatives, have been receiving increased attention.

The use of sulfonamide compounds in the treatment of malaria dates from the work of De Leon,¹²² who claimed to have treated 15 cases with Rubiazole successfully. This work and that of Hill and Goodwin¹²³ with Prontosil Soluble in this country have not been confirmed.¹²¹ The results obtained from sulfanilamide, sulfathiazole and sulfapyridine in simian malaria greatly stimulated research when the discovery was made that these drugs would sterilize infections of *P. knowlesi* in rhesus monkeys.¹²¹⁻¹²⁷ However, sulfanilamide and sulfathiazole did not effect complete sterilization of simian infections with *P. inui* and *P. cynomolgi*.^{72, 128} Nevertheless, if these drugs proved to be effective in human malaria, they could be used to treat cases refractory to other antimalarial drugs and also exert bactericidal and parasitocidal action in complicated cases with pneumonia or other acute infections. Unfortunately, the results to date are not in agreement—a possible indication of low antimalarial activity. Sulfanilamide and Prontosil have not proved effectual. Sulfapyridine has a temporary effect on the parasites, but relapses soon occur.^{129, 130} Coggeshall, Maier and Best¹³¹ have obtained promising results with promin and sulfadiazine. The antimalarial activity of promin was first demonstrated in 5 patients with induced malaria. The drug was later tried on 17 patients with naturally acquired

malaria (12 with *P. vivax* and 5 with *P. falciparum* infection) in Panama. Patients with malignant tertian malaria responded better than those with tertian infections. This result is in keeping with the selective action noted with sulfonamides on simian malaria, and led the authors to assume that these drugs have the greatest effect on the more virulent infections. Sulfadiazine was used on 13 Negroes (7 infected with *P. vivax*, 5 with *P. falciparum* and 1 with *P. malariae*). The drug showed a definite effect in 10 cases but failed in 3. Thus, the authors demonstrated considerable antimalarial activity with promin and sulfadiazine, but only point out the need for more extensive trials and assert that these two drugs are not substitutes for quinine and atabrine.

In the experimental and field trials with sulfonamide drugs in malaria, one disturbing factor stands out. These drugs often show highly variable effects on different species of *Plasmodium* in man, monkeys and birds. One can foresee the possibility that an effective drug against human malaria may be overlooked if the testing is done with avian or simian malaria. Furthermore, Coggeshall and Maier⁷² failed to find that inhibition of respiration in vitro by drugs was an index of chemotherapeutic efficiency with five species of *Plasmodium*. Consequently, thorough testing of drugs with antimalarial activity must be conducted on human as well as avian or simian malaria in order properly to evaluate their effectiveness. Admittedly, human trials are difficult, but at least efforts can be made in this direction.

Great promise of a new type of antimalarial drug has resulted from the discovery that amidino compounds have significant activity against malaria¹³² as well as trypanosomiasis, leishmaniasis, and infections with *Babesia canis* in dogs.¹³³ The amidino compounds tested thus far include undecane diamidine in tertian malaria and 4:4-diamidino stilbene (Stilbamidine) in tertian and malignant tertian infections. These drugs had definite and effective antimalarial activity, but trials have been too few to evaluate. The parasitocidal, bacteriostatic and bactericidal activity of the drugs is being tested widely, and the results appear to be encouraging.

Arsenical compounds and a number of drugs containing bismuth have been used for antimalarial treatment, but they are generally of value in controlling paroxysms rather than as curative drugs for the destruction of the parasites. Arsphenamine, neoarsphenamine, tryparsamide and Mapharsen are the drugs containing arsenic that have received the most attention. From the data presented by Winckel,¹³⁴ neoarsphenamine is useful in helping to control the course of fever in therapeutic tertian malaria. The results were not

always predictable, and relapses did occur in patients who were given malaria by infected mosquitoes. No effect was obtained, however, with induced quartan malaria, and references to its trial with malignant tertian infections have not been found. Mapharsen has been enthusiastically recommended for the treatment of induced tertian malaria, with a single injection terminating malaria in over 90 per cent of the cases, but eight to ten injections were said to eradicate the malaria permanently. Relapses occurred in only 2 of 24 cases,¹³⁵ but no mention was made of subinoculation of blood in normal persons to determine the radical cure claimed. Young and McLendon¹³⁶ failed to demonstrate curative effects of this drug on induced quartan malaria in Negro parietic patients. Tryparsamide also failed to affect the presence of circulating parasites and viability of blood in 8 patients. In fact, the warning was given that this drug should not be used to terminate induced malaria, because the blood remains infectious, and patients who are discharged may serve as a focus for transmission of the disease. Niven¹³⁷ confirmed the value of Mapharsen for the treatment of induced infections with *P. vivax*, but failed to find any effect against quartan and malignant tertian infections.

Bismuth compounds have been used for the treatment of naturally acquired malaria, but Schwartz¹³⁸ and Cole et al.¹³⁹ have made an important discovery in Thio-Bismol (sodium bismuth thioglycollate) for the clinical control of induced tertian malaria. These workers point out that patients undergoing malaria therapy frequently develop prolonged remittent fever or a double tertian type of infection with a daily paroxysm. The associated symptoms may vary, but physical exhaustion, vascular collapse, persistent vomiting, increasing anemia, rise in icteric index and a rise in the blood urea nitrogen are common. These symptoms need prompt control or treatment with quinine to stop the infection if the patient is to survive.

In the original series of 21 cases of induced tertian malaria receiving Thio-Bismol, the drug was found to possess antipyretic and antimalarial activity. One injection (0.20 gm.) intramuscularly given just before a chill controlled the fever in six to twelve hours and gave a patient an afebrile rest period for two days before the cycle resumed at a typical simple-tertian or forty-eight-hour interval. The untoward symptoms disappeared rapidly during the rest period, and the patient recovered sufficiently to withstand the resumption of paroxysms for their therapeutic effects. Repeated daily injections can be given if a longer rest period is desired, three such injections terminating paroxysms varying from five to thirty-nine days. Pa-

tients treated with Thio-Bismol to control the effects of induced malaria numbered 263, with a mortality of 2.2 per cent. This percentage is compared to the figures of Krauss,¹⁴⁰ in which there was an average mortality of 5.38 per cent among 8354 cases, and of Fong,¹⁴¹ in which there was a mortality of 3.35 per cent among 1012 patients. Consequently, the use of this drug in controlling therapeutic benign tertian malaria provides a significant and decidedly helpful advance.

No satisfactory explanation of the mode of action of Thio-Bismol has as yet been forthcoming. The evidence presented by Cole and his co-workers¹³⁹ substantiates their claim that the drug has antimalarial and antipyretic properties, but the antimalarial action appears to act only against a certain stage of the parasite. If the injection is given to a patient with simple tertian infection more than ten hours before the next expected chill, no effect is observed. The evidence that the drug is assimilated and excreted within twenty-four hours indicates that the therapeutic level in the blood stream is perhaps no longer existent at the time the parasites mature and begin their next asexual cycle. Yet the two-day rest period after injection of Thio-Bismol in remittent and double tertian infections indicates that the drug affects the half-grown parasites in the blood at the time of the injection immediately prior to the chill.

In a recent paper by Young et al.,¹⁴² an effort has been made to determine the effect of Thio-Bismol on various asexual stages of *P. vivax* and also to test the effect of the drug on *P. malariae* and *P. falciparum*. When 0.1 or 0.2 gm. of the drug was injected intramuscularly sixteen to twenty-eight hours after the last paroxysm caused by tertian parasites, future paroxysms by that brood were inhibited. Injections at other hours failed to have any effect. The half-grown parasites decreased in number and in stained films they appeared shrunken, fragmentary, irregularly stained and even free in the plasma of the blood. Yet, according to the opinion of the authors, this degeneration could not alone account for the sharp drop in the number of parasites. The experiments with induced quartan, and malignant tertian infections failed to demonstrate any clearcut action against *P. malariae*, and *P. falciparum* showed the least response of all to Thio-Bismol.

Another interesting and valuable observation by these same authors, was the prompt therapeutic response obtained when Thio-Bismol was injected on the day that the administration of quinine was begun to terminate a tertian infection. The Thio-Bismol inhibited the next paroxysm and the quinine controlled the infection, thus a quicker therapeutic response was obtained than when quinine was used alone.

In passing it should be noted that, here again, a drug has proved to be effective against stages of one species of malaria parasite and not against others. Thus the evidence continues to indicate the individuality of the plasmodia pathogenic for man and the need for pointing research studies toward a solution of the physiologic and biochemical differences that exist between species.

MALARIA IN RETURNING TROOPS

Finally, the following question, frequently asked during recent months, deserves brief consideration: Are troops returning to this country from endemic malarious areas a serious threat to the public health? Even now, frequent references are being made to relapses of malaria in men who have returned from the fighting fronts in the Southwest Pacific and Africa.

An analysis of the serious potentialities reveals that the following factors will play a role in the spread of tropical diseases, including malaria, from returning troops: the time of year when troops return; the presence in the area of necessary vectors for transmission of disease; the type of sanitation in rural or urban communities to which men return; and the occupation taken up by the returned soldier or sailor. The first three factors are the most important ones. If a person harboring malarial parasites in his blood returns during the breeding season of transmitting anopheline mosquitoes, transmission can take place. However, if no anophelines are breeding or can gain access to the infected person, no transmission can occur. With regard to the presence of transmitting vectors during the summer, anophelines that can transmit malaria occur in many of our northern states, including Massachusetts, the only reason for the disappearance of malaria being the absence of human infection. Small epidemics have occurred in scattered northern states in recent years, and future outbreaks may be expected. The explanation of the third factor—sanitation—is obvious. Communities containing numerous breeding places for anophelines, with inadequate screening of houses, a low economic status and poor medical care and supervision are likely areas for the transmission of malaria. Such areas provide the greatest chance for tropical and virulent strains of malaria to gain a foothold.

The experience in England during and after World War I indicates that malignant tertian malaria dies out after approximately one year at that latitude, leaving only endemic benign tertian malaria. In Macedonia, malignant tertian malaria was the most prevalent type among the troops. When these troops returned to England and relapses developed, — approximately 14,000 in 1919,¹⁴³ — the anophelines apparently failed to transmit the infection, because the temperature and hu-

midity requirements for the completion of the developmental cycle did not obtain. Reasons for this failure are well known to malariologists, for malignant tertian malaria is seldom found in regions having an average summer temperature lower than 21°C. (70°F.) and an average winter temperature lower than 9°C. (48°F.). If the infection is brought into such areas, small epidemics may occur, but eventually the disease dies out. Consequently, the major problem with returning troops is to recognize and make an accurate and speedy diagnosis of malaria in all infected persons. Since it is desired to prevent the transmission of new malarial strains in this country, and since there is no need for these men to acquire immunity, a radical cure should be the aim of every practitioner treating such infections.

NEW HAMPSHIRE MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND FIFTY-SECOND
ANNIVERSARY

House of Delegates, May 10 and 11, 1943

THE House of Delegates convened at the Hotel Carpenter, Manchester, on May 10, 1943, at 7:30 p.m., with Speaker Charles H. Parsons, of Concord, presiding.

The following members answered the roll call.

The President, *ex-officio*
The Vice-President, *ex-officio*
The Secretary-Treasurer, *ex-officio*
Park R. Hoyt, Laconia
Raymond J. Turley, Meredith
W. J. Paul Dye, Wolfeboro
Francis J. C. Dube, Center Ossipee
Walter F. Taylor, Keene
A. C. Johnston, Keene (appointed as alternate for
Norman H. Robertson)
Leander P. Beaudoin, Berlin
Arthur B. Sharples, Groveton
Arthur W. Burnham, Lebanon
Leslie K. Sycamore, Hanover
David W. Parker, Manchester (appointed as alternate
for George V. Fiske)
Deering G. Smith, Nashua
George C. Wilkins, Manchester (appointed as alter-
nate for Charles H. Cutler)
George F. Dwinell, Manchester (appointed as alter-
nate for Clarence E. Dunbar)
Luther A. March, Nashua
Edward V. Putnam, Warner
Robert M. Lake, Concord
Frederick S. Gray, Portsmouth
Anthony E. Peters, Portsmouth
Edwin D. Lee, Exeter
Roland J. Bennett, Dover
George G. McGregor, Durham
Emery M. Fitch, Claremont (appointed as alternate
for Henry C. Sanders, Jr.)
B. Read Lewin, Claremont

The Speaker declared a quorum present, and appointed the Credentials Committee as follows: Drs. McGregor (chairman), Lake and Lee. Dr. McGregor reported that the credentials were in order.

The Speaker appointed the Committee on Officers' Reports as follows: Drs. Peters (chairman), Smith and Sanders. He appointed the Committee on Communications and Memorials as follows: Drs. Putnam (chairman), Campbell and Taylor.

Upon motion duly made and seconded, it was voted to omit the reading of the previous minutes, because of the publishing of the proceedings.

The secretary-treasurer, Dr. Carleton R. Metcalf, presented his report.

CARLETON R. METCALF, *Secretary-Treasurer*

Dr. Lord, a trustee, made a statement of fact regarding finances, as follows:

Dr. Metcalf has said that our funds are going downhill pretty fast. I think you know that the Society has

something over \$20,000 in different funds, and most of the funds are earmarked for special purposes, such as the Pray Fund and the Benevolence Fund. But there is the fund that we call the General Fund, totaling about \$10,000, from which we can draw in emergencies. I should like to tell you a little of what has happened to the Fund.

On May 1, 1940, the date on which the Trustees' report is made up, the General Fund had on hand approximately \$11,800. On May 1, 1941, it had on hand approximately \$10,897. The next year,—this will have to be stated as of January, 1942, because we have changed our period, so that it is less than a year,—the Fund had on hand approximately \$10,000, which is \$800 less than the year before. In January, 1943, it had on hand approximately \$9192, a further decrease of \$800. From January, 1943, to May 10, 1943, it lost about \$300 more. Thus the Fund is continually going downhill. The total has diminished in a little over three years (from May 1, 1940, to May 10, 1943) from \$11,800 to \$8000, or about \$3000.

The reason for this diminution is as follows: Ordinarily, the General Fund is not used for the expenses of the Society, because those expenses are handled from our ordinary income, but when an emergency arises, the Society can vote to spend certain sums. The first year, \$1000 was put into the General Fund itself to raise the total. The next year, 1941, we spent \$1000 and thereby increased the Benevolence Fund. In 1942, we spent \$1000 for the sesquicentennial celebration. During the past year, for the reasons that Dr. Metcalf gave you, we spent \$1100 extra, and since January 1, 1943, we have added another \$356, which is for the Procurement and Assignment Service. By that means, our total has been reduced to \$3000.

The income of the General Fund last year was \$223. Now, if our expenses for next year are something like \$1000 or \$1100, such as we paid this year for general expenses, plus the Procurement and Assignment Service,—if the latter costs what it did this year,—the total expenses will be about \$7450. The income being a little over \$200, we shall have a net loss of about \$1250 during the coming year, if the war keeps on.

I understand also that we have 551 members. The number of men in the Service is, I believe, 114. This leaves about 440 men who are paying dues for 551 members. If the net loss for the coming year is \$1250, we shall have to pay \$3 per man to make up for it. Do you want to keep the fund up to an approximate \$10,000? If you do, you will have to do something to bolster it up.

Secretary Metcalf replied as follows:

We hope to economize to the following extent this year: The Procurement and Assignment Service, according to Dr. Deering Smith, will be much less expensive this year than it has been in the past. Also, we are having a one-day meeting, which is less expensive than a two-day meeting. We have chosen all our speakers from New England, so that we are saving on the traveling expenses of men from outside cities like Chicago, Rochester, Minnesota, Philadelphia and New York. The Auxiliary has ordinarily received \$100 toward its meeting, but this year it is not receiving anything. My only other suggestion is the one

that I made in my address which is the elimination of the *New England Journal of Medicine*. This would mean a saving of about \$600 a year, but in the past this step has been considered penny wise and pound foolish.

Dr Johnston suggested that the dues be raised by the amount specified by Dr Lord, to keep the organization going as before.

Dr Burnham asked what was the use of having a large General Fund if it was not to be spent in such times as these. He saw no occasion for alarm. He thought that it was permissible to raise the dues if necessary, but why was it essential to have \$10,000 in the General Fund? Even if the Society was now spending more than usual, and the Fund was going down, he saw nothing to worry about unless it should drop to about \$1000, in which event it could be built up. The situation would probably adjust itself after a fashion. The commonsense thing to do was to let the Fund stay as it was unless it fell to a low level, when the members could be assessed \$2 or \$3 extra to bring the Fund up again.

The Speaker then appointed the Committee on Nominations as follows: Drs Dye (chairman), Burnham, Wilkins, Fitch and Beaudoin.

The Committee on Officers' Reports commended the faithful and efficient work of the Secretary, Treasurer, and the chairman, Dr Peters, moved the adoption of that portion of the report. This motion was duly seconded and was carried.

Dr Peters then spoke as follows:

The committee recognizes the continuing decrease in revenue of the Society, due to the war, which is being partially offset by the economies effected by this one-day meeting. It is recommended that the *New England Journal of Medicine* be continued to be sent to all members, including those who are in the Service.

Serious consideration as to the raising of the dues must be given, because it does not seem wise to draw on the General Fund too heavily to make up our deficit.

Dr Peters moved the adoption of this part of the report, and the motion, duly seconded, was carried.

Dr Peters then added that the committee recommended that the Committee on Nominations this year exclude members in the Service, although they will be properly carried on the membership lists. He moved the adoption of this part of the report, and the motion, duly seconded, was carried.

Reports of Councilors

BELKNAP COUNTY

The Belknap County Medical Society held six meetings from November to April, inclusive. The meetings were

held at the Laconia Tavern. Dinners were served and were followed by programs. The meetings were well attended, the men from the north coming when it must have been a great effort.

The society has 7 men in the armed services. This in a small society is very noticeable, throwing a decided burden on those in active practice.

The society has 37 members.

C S ALDOTT

CARROLL COUNTY

We have a very small group with infrequent meetings of the county society as a whole but fairly frequent usually monthly, assemblies of the several hospital staffs.

The present report largely consists of an account of the annual meeting of the society held on April 14, 1943 at Huggins Hospital, Wolfeboro. The exigencies of the war, as expressed by restrictions in travel and more work for the fewer physicians left at home, have prevented more meetings of our society this year. It was unanimously voted that the secretary remit \$1 per capita of the membership of the society to the National Physicians Committee as a contribution and as an expression of approval of the fine work it has done.

A motion that the society go on record as approving the Medical Insurance and Enabling Act now under consideration by the New Hampshire State Legislature was unanimously carried.

The following officers for the ensuing year were unanimously elected: Drs F J C Dube and W J P Dye delegates to the annual meeting of the New Hampshire Medical Society. Dr Dube, president, Dr Ralph W Tuttle vice president, and Dr Charles E Smith, secretary treasurer.

A talk was given by Dr Dye covering the war sessions meeting of the American College of Surgeons held in Boston on March 15, 1943. Various medical facts concerning military and naval medicine that had brought forth new procedures because of wartime problems were discussed.

A thorough discussion of the value of the Stader skeletal traction, reduction and immobilizing splint in which the patients have free motion of the joints above and below the fracture and are largely ambulatory, was presented through reports of the Navy medical officers who participated in the Boston meeting. It appears that this may be a great advance in the treatment of fractures provided the excellent results shown in the large number of cases now treated and under observation by the Navy Medical Corps continue to be obtained.

The wartime trends of medical education, whereby all medical students will be enlisted in a branch of the armed forces with their tuition paid by the Government were brought out. Further mention was made of the help that nurses aides and other voluntary organizations are giving to depleted hospital personnel.

It was stressed that Civilian Defense has accomplished a great deal in the organization of communities for disasters, as aptly proved by the excellent management of the Coconut Grove fire and it was hoped that practice interest and study would be continued along these lines.

At the same meeting Dr Frank H. Lahey, chairman of the Directing Board of the Procurement and Assignment Service, gave some interesting and instructive remarks concerning the operations of this committee. He stated that Massachusetts, Connecticut and New York

which are largely metropolitan and urban districts, were considerably behind in their quotas of physicians for the armed services. It was noted that the medical profession had been given the privilege of classifying its own members as available or essential, and to date the majority of men so classified as available, except in the three states above mentioned, had promptly voluntarily applied for their commissions, so that quotas for last year were met. Dr. Lahey voiced the hope that quotas would be met this year in the same voluntary fashion, so that the members of the medical profession would prove worthy of the privileges conferred upon them, but he warned that if quotas were not met, some compulsory method might be instituted to supply Army and Navy medical officers.

W. J. PAUL DYE

CHESHIRE COUNTY

The Cheshire County Medical Society held two well-attended meetings during the past year.

The spring meeting was held at the Eliot Community Hospital. At this meeting papers were read, and discussions followed each paper. After the meeting, dinner was served by the hospital to all members of the society.

At the second meeting no papers were read but the time was given to discussion of local and state medical questions. Six members of our society have joined the armed forces, 5 from Keene and 1 from Troy.

The secretary reported that all the doctors in the county belong to the society and that all are in good standing.

JOHN J. BROSNAHAN

COOS COUNTY

The officers of the society, after conferring together, decided not to hold a meeting this year, largely owing to difficulties of travel and the unavailability of a speaker.

The society has 6 members serving in the armed forces, and there are 2 nonmembers so engaged.

The former officers are serving the society for another year.

RICHARD E. WILDER

GRAFTON COUNTY

The Grafton County Medical Society has continued its policy of holding two meetings each year.

At the regular business meeting held at Hanover in the fall, 3 new members were elected. It was voted to continue participation in the program for medical care sponsored by the Farm Security Administration. A contribution of \$75 to the National Physicians' Committee was voted.

A discussion on "Virus Pneumonia" was presented by Drs. Sven Gundersen and Colin C. Stewart, Jr., of the Hitchcock Clinic.

The spring meeting will be held at Hanover on April 28, 1943. The program will consist of a discussion on infantile paralysis.

ARTHUR W. BURNHAM

HILLSBOROUGH COUNTY

The Hillsborough County Medical Society has changed its former time of meeting, and has instituted evening meetings following a dinner.

The business meeting was held in the fall at Manchester, New Hampshire, with 75 members present. New officers were elected as follows: Dr. G. Hoffses, president;

and Dr. S. Fraser, vice-president. Dr. Charles Parsons, head of Civilian Defense for New Hampshire, gave a brief outline of the work in this state. President Thibodeau introduced Dr. Dudley Ricker, regional medical officer, who gave a fine talk on preparations being made for civilian defense in this corps area.

The 1943 spring meeting was held at the Nashua Country Club, with Dr. Hoffses presiding. Reports showed that we have 146 members and that 34 of these are in the armed services, which is about 25 per cent of the membership.

The medical program was conducted by the Medical Department of Grenier Field, and was participated in by Lieutenant-Colonel Fresh, Major Hubbard and Lieutenant Reitz, Captain Hardenbrook, Captain Driggs and Lieutenant Hermann. Captain Coughlin, Major Tate, Major Babson and Captain Butterfield also participated. This proved to be a most interesting program, and the society suggests that some other county society put on a similar program.

During the past year we have lost 2 members: Dr. Herbert S. Hutchinson, of Milford, the second oldest member in the society, and Dr. Norman D. Webber, of Manchester.

We have the largest membership in the history of the society, and attendance at our last meeting excelled all others.

C. O. COBURN

MERRIMACK COUNTY

A social meeting was held on July 7, 1942, at the Franklin Country Club, with 25 members present. A demonstration of resuscitation was given. Dr. Chaney Adams acknowledged a gift as a member of fifty years' practice.

At a meeting on October 6, 1942, at the Eagle Hotel, Concord, Major W. W. Babson, M.C., U.S.A., discussed the present-day treatment of burns.

The annual meeting was held on January 5, 1943, at the Eagle Hotel, Concord. It was voted to send a message of sympathy to the family of Dr. A. K. Day. Three new members were admitted to the society. Dr. Metcalf spoke on group hospitalization.

A meeting was held on April 6, 1943, at the Eagle Hotel, Concord. It was voted to hold the summer meeting at New London. Major John S. Wheeler, state medical director of Selective Service, discussed some medical problems in connection with his organization. Mr. Spaulding, New Hampshire director of the Blue Cross, explained the system of hospitalization.

The following members are in the Service: Donald Barton, Lee C. Bird, John H. Branson, Warren H. Butterfield, Eugene Chamberlain, Joseph M. Clough, Carl A. Dahlgren, Raymond P. Galloway, MacLean J. Gill, Thomas J. Halligan, Oliver S. Hayward, Philip M. L. Forsberg, Harold D. Levine, Joseph McCarthy, J. K. McLeod, Herbert B. Messinger, J. Dunbar Shields, Ellsworth M. Tracy, Jules Weinberg and John S. Wheeler.

WARREN H. BUTTERFIELD

ROCKINGHAM COUNTY

The annual meeting of the Rockingham County Medical Society was held on October 28, 1942, at the Portsmouth Hospital. Twenty-six members were present. After the usual business meeting, lunch was served by the hospital.

Two interesting papers were presented one by Dr J F Holmes, Manchester, on Shipping Rib Cartilage, and the other by Lieutenant Commander E Ross Mintz (MC), USNR, on Some Urologic Aspects

The date for our spring meeting has not been selected

CLEON W COYNE

STRAFFORD COUNTY

For the year 1942 the society had 28 active and 6 affiliate members. Four members are in the United States Army and 1 is serving with Pan American Airways in Africa.

The annual meeting was held on October 28, 1942, at the Lincoln House, Dover. There were 23 members and guests present. Dr H Bristol Nelson of the Boston Lying-in Hospital spoke on Everyday Problems in Obstetrics.

The spring meeting, to be held on April 28, is now being planned. It is expected that we shall be forced to accept educational films in lieu of a speaker.

In accordance with the action taken last year in the House of Delegates of the New Hampshire Medical Society, \$1 for every active member has been sent to the National Physicians Committee.

There were no deaths among our members during the fiscal year, nor were there applications for membership. There is one request for transfer from York County (Maine) to be acted on at our next meeting.

J A HINTER

SULLIVAN COUNTY

The Sullivan County Medical Society held three meetings during the past year.

The first meeting, held in Claremont, consisted of the election of officers and routine business, including a discussion of the man power problem, in view of doing our part in supplying doctors for the armed forces.

The second meeting, in June, was a joint meeting with the Crawford County Society, addressed by Dr Deering Smith on Procurement and Assignment.

The third meeting in Claremont was a symposium on infectious diseases, led by Dr Edward Pease of Boston. These meetings were all well attended and much interest was shown in keeping the society in touch with the state problems.

EMERY M FITCH

Dr Putnam then made his report as chairman of the Committee on Communications and Memorials. He first presented a communication from the New Hampshire State Department of Public Welfare.

Dear Dr Metcalf,

In accordance with an established plan of rotation Dr John A Coyle, of Hanover and Dr Raymond Ingalls of Berlin are retiring as members of the Medical Advisory Committee on Eye Conditions, which assists the Department of Public Welfare in adequately handling medical matters in connection with the state's blind and prevention-of-blindness program.

To replace Dr Coyle and Dr Ingalls the department recommends Dr Hermann Burian, of Hanover, and Dr Edward McGee, of Berlin. Both doctors have accepted our invitation to serve. In order that

the records may be kept up to date and the state medical society may be kept informed on all departmental matters relating to the medical-care field I am writing to request that the House of Delegates approve Dr McGees and Dr Burian's acceptance of an appointment to this committee.

(Signed) ELMER V ANDREWS
Commissioner

On motion duly made and seconded, it was voted that the House of Delegates approve Dr McGee's and Dr Burian's acceptance of their appointment to the Medical Advisory Committee on Eye Conditions.

Dr Putnam then presented a letter from the New Hampshire Hospitalization Service.

89 North Main Street, Concord
January 17 1943

Dear Dr Metcalf,

It is the desire of the New Hampshire Hospitalization Service to secure the full approval of the New Hampshire Medical Society for its activities in the State.

As you know, the Blue Cross is established as a nonprofit corporation, is operated as a public service and has met all the requirements of the American Hospital Association and has received the approval of that organization. It has been approved by the New Hampshire Hospital Association.

We would also like your permission to inform the public of your approval.

If there are details of our corporate structure or purpose on which you desire information, I would be very glad to provide it.

(Signed) R S SPILLING
Executive Director

Dr Putnam recommended the approval of the hospitalization plan and the motion, duly seconded, was carried.

Dr Putnam then presented a letter from the National Conference on Medical Service. He said that the main purpose of the letter seemed to be the seeking of approval of a resolution that would authorize a Committee on Medical Service of the American Medical Association, which would have some sort of liaison office in Washington for the purpose of improving medical service care. The letter was accompanied by the following resolution.

WHEREAS, Social and economic changes have altered the lives of our citizens, and the federal government has found it necessary to issue directives from time to time as physicians believe that it is our duty to take a more active part in the creation of such regulations as affect the practice of medicine, therefore, be it

RESOLVED That this National Conference on Medical Service go on record as favoring the immediate

development of a stronger national economic and legislative policy governing the practice of medicine and that such a policy be integrated with each state and county, and be it further

RESOLVED, That the expression of this National Conference on Medical Service be submitted to the Board of Trustees of the American Medical Association, advising them that this resolution, or a similar one, will be submitted to the delegates of the American Medical Association at their next annual meeting.

Dr. Putnam said that the Committee on Communications and Memorials had no recommendations on this particular letter. On questioning by the speaker, Dr. D. G. Smith replied that he had nothing to say regarding the communication. Dr. Putnam added that, included with their letter was a resolution that they proposed to the House of Delegates of the American Medical Association, to be submitted to that body at the annual meeting. (Dr. Putnam then read the letter.)

In answer to a question, Dr. Putnam stated that approval of this resolution was sought. It was to be forwarded to the National Conference of Medical Service, and the resolution would then be presented to the House of Delegates of the American Medical Association at its annual meeting.

Dr. Dwinell expressed the opinion that the American Medical Association was opposed to the presence of any legislative or lobbying organization in Washington. He believed that the purpose of the National Conference on Medical Service was to place in Washington some such group that was not connected with the American Medical Association.

The speaker requested Dr. Putnam to talk the matter over with Dr. D. G. Smith and make a report in the morning.

Dr. Putnam, speaking in behalf of the Committee on Communications and Memorials, then recommended that the House of Delegates of the Society be put on record as favoring the basic principle of having a liaison representative in Washington. This he thought should be done either through existing committees or in a manner deemed best by the American Medical Association.

Upon motion duly made and seconded, the report of the Committee on Communications and Memorials was accepted.

Dr. Woodman then made his report as chairman of the Committee on Amendments to the Constitution and By-Laws, as follows:

Last year, there were two changes in the by-laws which would change the wording in two sections. One was that Chapter VIII, Section 10, be amended to read as follows:

The Committee on Mental Hygiene shall consist of three members, whose duties shall be to study this special subject, co-operate as far as possible with the heads of the state institutions under medical supervision, and report to the Society.

This leaves out the word "Social" and makes it strictly a committee on mental hygiene.

Then, there was another change; it was recommended that the Committee on Medical Education and Hospitals should consist of three members. This change was in Section 12.

Those were changes in the by-laws, and they were consummated by being permitted to lie over one day.

A change in the constitution proposed by Dr. Smith is to the effect that Article XII be deleted. Article XII reads as follows:

Article XII. *New England Medical Council.* This Society shall be privileged through its House of Delegates to join with other New England state medical societies, and to participate in the activities of the New England Medical Council.

The New Hampshire Medical Society shall be represented in this body by the President, Secretary, Treasurer and three delegates-at-large. The three delegates-at-large shall be appointed by the President, one for one year, one for two years, one for three years; annually thereafter he shall appoint one for three years.

This, apparently, should be acted on at this meeting.

A change suggested by Dr. Wilkins is that Article XIII of the constitution be made Article XII. This should also be acted on at this meeting.

On the recommendation of Dr. Peters of the Committee on Officers' Reports, it was voted that the report of the Committee on Amendments to the Constitution and By-Laws be accepted as read.

On motion of Dr. Wilkins, the changes in the constitution as presented by Dr. Woodman were adopted.

A verbal report of the Committee on Child Health by Dr. Colin C. Stewart, who was unable to file a written report, was accepted on the recommendation of the Committee on Officers' Reports.

The report of the Committee on the Control of Cancer was presented by the chairman, Dr. Wilkins.

Report of the Committee on the Control of Cancer

Three short letters giving information on three pertinent aspects of cancer control were sent to every physician in New Hampshire. Of the three letters, perhaps the most important for reference filing was a concise but comprehensive discussion of biopsy methods, instruction in taking biopsies, where to take them from and how they should be prepared if mailed to a laboratory. The importance of a brief but good history, with the patient's name, age and a description of the tumor, was noted. Another letter described proper methods of examining and taking biopsies from women with abnormal flowing. The purpose of this letter was to explain not

only how to determine the cause of bleeding but to state emphatically that no patient should be treated with x-ray therapy for abnormal bleeding without preliminary examination of the cervix, if no disease was discovered there, the uterus should be curetted under general anesthesia and a pathological report should be awaited before proceeding with any treatment. Too many cases have been observed where cancer of the cervix or fundus has not been discovered until too late for successful treatment, both the patient and the doctor having been lulled into a feeling of false security because irradiation temporarily stopped flowing. The third letter discussed carcinoma of the vulva and stressed particularly the necessity of a radical vulvectomy in all cases, with later node dissection on the affected side. It was explained that incomplete operation almost invariably is followed by recurrence.

We hope these letters may be useful in bringing something new or something that has been forgotten, to the attention of the busy physician or surgeon. The subjects that have been discussed in all our letters since 1934 have been on phases of cancer diagnosis or treatment that, from observations made in clinics and laboratories have shown the need for further education of the physician.

The fourteen diagnostic clinics and treatment centers have continued their excellent work. Twelve years ago there were one cancer clinic, one supply of radium and three deep-therapy x-ray machines in the state. Today there are fourteen clinics, of which seven are treatment centers. There are 800 mg of radium available and there are ten deep-therapy machines. New Hampshire has more cancer clinics per population than any other state and eleven of the fourteen clinics have been approved by the American College of Surgeons. Transportation difficulties have reduced the number of patients coming to the clinic, not so much among those with cancer, but it has reduced the number of those not actually having cancer, and unfortunately it is difficult for patients who have been treated to return regularly for check-ups. Last year 54 per cent of the new patients examined in the clinics had cancer compared with 36 per cent in 1934.

The Women's Field Army continues its important and notable work in carrying out its educational program among the laity, through the distribution of thousands of pamphlets, arranging cancer talks before groups, radio broadcasts and moving pictures before groups and in schools. Many physicians have given talks before groups and on the radio. The Women's Field Army also assumes the expenses of transportation of many indigent patients to and from clinics and hospitals. Another activity is making surgical dressings for indigent cancer patients. These dressings are made from old cotton and linen combined with cellulose.

The Executive Committee of the Women's Field Army will soon consider the advisability of establishing a fund from which amounts may be drawn to cover the expenses incident to a three or four weeks training course in cancer diagnosis and treatment. It is suggested that this be offered to physicians associated with our cancer clinics and selected by the hospital staffs. It is believed that the use of this money to carry on further education of physicians interested in cancer and its treatment would be an admirable way to return to the citizens of the state some of the investments made in the work of the Women's Field Army. This will require acceptance of the plan by the hospitals, the American Society for the Control of

Cancer and certain teaching hospitals with large cancer services.

The Women's Field Army constantly urges periodic physical examinations as one way of discovering cancer early, and the medical profession can aid this recommendation by hearty approval of the principle and by giving a really thorough and comprehensive examination when requested.

Your committee spent \$40.80 for printing stationery and postage. The balance of our \$50 appropriation has been returned to the treasurer. We request an appropriation of \$50 for the coming year.

GEORGE C WILKINS, *Chairman*

RALPH E MILLER

GEORGE F DWINELL, *Secretary*

Dr Peters, speaking for the Committee on Officers' Reports, recommended that the Committee on the Control of Cancer encourage the proposal that physicians associated with cancer clinics be assisted in the manner contemplated by the Executive Committee of the Women's Field Army, which would cover expenses for a three to four weeks' training in cancer diagnosis and treatment. The motion was carried.

The Committee on Officers' Reports further recommended that the request for an appropriation of \$50 for the ensuing year be approved. The motion was also carried.

The report of the Committee on Medical Economics was made by Dr Leslie K. Sycamore.

Report of the Committee on Medical Economics

National Physicians' Committee. The work of the National Physicians' Committee for the Extension of Medical Service is of continuing importance and your committee makes the same recommendation as last year that a contribution of \$1 per capita be made by each county society, to be transmitted to the National Physicians' Committee through the treasurer of the New Hampshire Medical Society.

Prepayment Medical Service. As directed by the House of Delegates at its last session, an enabling act was introduced into the present session of the Legislature and has been passed by both houses. This act permits the establishment, under regulation of the State Commissioner of Insurance, of a medical service corporation for furnishing medical care on a prepayment insurance basis. Your committee has continued its study of such plans as are now in existence and recommends that a definite plan be drawn up for the establishment of a medical service corporation in New Hampshire, such plan to be submitted to the next meeting of the House of Delegates for its approval.

Medical Care Program for Farm Security Clients. This program continues to function satisfactorily in Grafton and Cheshire counties with 100 per cent payment of bill for physicians' services during 1942.

LESLIE K SYCAMORE

FRANCIS J C DUBE

Dr Peters for the Committee on Officers' Reports moved the adoption of that portion of the report relating to the work of the National Physicians'

Committee. The motion, duly seconded, was carried.

Dr. Peters said that in view of the fact that the enabling act has since become a law, it was recommended by the Committee on Officers' Reports that a definite plan be drawn up by the Committee on Medical Economics and Mr. Sullo-way for the establishment of a medical-service corporation in New Hampshire and that such plan be submitted to the next session of the House of Delegates for its approval. He moved the adoption of this portion of the report.

Dr. Metcalf then spoke as follows:

This enabling act, which has been signed by the Governor, permits any corporation to work out this particular problem of prepayment of all medical care on the insurance basis under the supervision of the Commissioner of Insurance. The Blue Cross, which has a hospitalization plan, is interested in this. I do not know, if they undertake it, when they will want to do so. It is perfectly possible that they might like to get going before the first of the year, or before the expiration of another year.

If any corporation wishes to undertake this plan, it may be desirable to get in touch with it and have a perfectly definite plan worked out before the next meeting of the Society. In other words, it is going to delay the whole thing a year if we turn it over to the Committee on Medical Economics and have them report a year from now, and then work out something with some corporation. If any plan is adopted, of course, it must be one that will appeal to the doctors, and that will have a sufficiently low premium rate so that it will appeal to the public, and there are many details with which the insurance companies are familiar that must be incorporated and must be studied. Shall these patients be patients in hospitals? Shall such a plan provide for house visits and office visits? Shall it provide for x-ray work? All these details have to be worked out.

The thing has to be on a basis which can be sold to the public in groups and which will also ensure a fee that is adequate for the doctor, and that will not be any cut-rate proposition.

I do not know the best way to go about it. There is a question in my mind whether the thing ought not to be expedited as much as it can be, if the plan is going to come to fruition.

Dr. Wilkins thought that the simplest procedure would be to work with the Blue Cross representatives who were handling the hospitalization problem in New Hampshire. He said that in Massachusetts, the Blue Shield was being conducted through the office of the Blue Cross, and that since prepayment hospital insurance was already in operation in the State, he was inclined to think that probably it would work out better if co-operation could be obtained with that group to carry on this work.

Dr. Sycamore said that it was the opinion of the Committee on Medical Economics that to draw up such a program would require considerable time and that it could be expedited if necessary. It was felt that it was an important enough program, so far as the medical profession was concerned, to be brought before the House of Delegates and approved before any such plan could be put forth. If the House of Delegates thought that such a program should be expedited, a special meeting of the House could be called for that purpose. It was a part of the provision of the enabling act that the Trustees must be approved by the New Hampshire Medical Society, and this would have to be done before any such plan could be started. It had been the experience in places where such plans were functioning that the simplest way to handle them was through the Blue Cross, if that organization was working in the state in which the plan was introduced. Such a procedure could probably be worked out in New Hampshire.

Secretary Metcalf said that after talking with Mr. Spaulding, the Blue Cross representative, he had decided that any committee—the Committee on Medical Economics, if it drew up the plan—ought to go over the situation with the insurance people, because Mr. Spaulding had pointed out to him various things from an insurance standpoint that had not occurred to him. The plan might have to be worked out through the county societies rather than through the State Society, because the bill specified that 50 per cent of the men in a given area must sign up for the plan if it was to be put into effect in that area. He did not know what an area was, but supposed that a logical one would be a county. He suggested that the Committee on Medical Economics might go over the whole thing with the Blue Cross and draw up some scheme that they thought was workable and that the committee thought would appeal to the doctors. They could determine what an area was and so forth, so that when the plan was reported to the Society a year later, it would be a full-fledged one that would stand up under criticism.

Dr. Sycamore replied that that was the intention of the recommendation.

Dr. Peters asked when the plan must be reported, and whether it was proposed to hold a special session. Secretary Metcalf thought that this question would rest with the Committee on Medical Economics. A special session would be difficult to organize.

Dr. D.-G. Smith proposed that a copy of the plan be submitted to the House of Delegates in

advance of the next session so that it would have an opportunity to go over it.

Dr. Wilkins pointed out that this would cause too much delay, and proposed that the committee study the proposal and make a report on it. They might be able to make a report in six months and send a printed report to the House of Delegates, and possibly get some action. This would be preferable to delaying the matter, for a whole year.

President Rock suggested that the Committee on Medical Economics and the officers of the Society take the matter up and make an early report.

Dr. Peters felt sure that if such an amendment was made, the Committee on Officers' Reports would concur.

Secretary Metcalf asked whether the time element could be omitted, and the committee and officers asked to report either at a special session or at the next regular session.

Dr. Wilkins thought that this would be acceptable.

Speaker Parsons asked Dr. Smith to withdraw his motion, with Dr. Dye's permission, and restate it with this qualification.

Dr. Smith agreed that the next session might be a regular session or a special session.

Dr. Wilkins said that he believed the President's suggestion should be embodied and that the

Committee and the Officers of the Society should work on this proposition.

Dr. Peters presented a new recommendation, namely, that a definite plan be drawn up by the Committee on Medical Economics, with the officers of the Society, for the establishment of a medical-service corporation in New Hampshire, such a plan to be reported as early as possible.

A member asked whether the plan would have to be ratified by the Society as a whole or simply by the Delegates. Speaker Parsons replied that ratification would be by the Delegates only, since they are the governing body.

Dr. Fitch agreed with the Secretary that a special session was difficult to manage, and asked whether, if the matter could be expedited so that it could be handled by the committee and the officers, as adequate an opinion could be obtained from the Society as would be done by calling a special session.

Dr. Dye asked whether it was possible to decide by a nonassembled vote. Dr. Smith then moved that the plan after being proposed by the committee be submitted to the members of the House of Delegates for their approval or disapproval, by a nonassembled vote, and that the House of Delegates authorize the action of the members in this nonassembled group in advance. The motion, duly seconded, was carried.

CASE 29331

PRESENTATION OF CASE

A seventy-five-year-old physician entered the hospital because of a painless mass in the upper abdomen.

He had been in excellent health until eight years prior to admission, at which time, while riding in the back seat of a car, he received a heavy jostling in going over a bump; he felt as if something had been torn loose in his upper abdomen. Three years before entry he noted a firm mass in the epigastrium. Two years before entry he overworked during the remodeling of his house and had an attack of midepigastria pain, which radiated toward both flanks. This was followed by several attacks of faintness and sweating, one of which occurred after a home obstetric case in which the delivery was performed on a low bed, and was associated with some vertigo and ringing and pulsating in the ears without deafness. He was seen by a physician, who advised rest. This he did for two weeks but then resumed his normal busy life. He was free of pain until fourteen months before admission, when he again strained himself while working about his car. He had epigastric pain radiating to the right and left. This time the pain was much severer. It gradually subsided, however, after he had rested for a week. In the interim the abdominal tumor had steadily increased in size so that when he sat in certain positions he had an annoying sensation. There was no history of disturbances of appetite or bowel movements. No weight loss was noted.

He had had typhoid fever at the age of twenty-five.

Physical examination showed a tall, large-boned man in no discomfort. Hyperkeratotic lesions were present over the dorsum of both hands. The lungs were hyperresonant. The cardiac borders could not be determined because of emphysema. The heart sounds were normal in volume, rate and rhythm. There was a blowing systolic murmur, best heard in the aortic area. The second sound was snapping. The upper abdomen was protuberant. A large, firm, irregular, movable mass

about 15 cm. in diameter was palpable in the upper midabdomen. It was nontender and the abdominal wall was movable over it. It transmitted strong aortic pulsations.

The blood pressure was 170 systolic, 100 diastolic. The pulse was 80 and of large volume. The temperature and respirations were normal.

On the evening of admission, about three hours after having been examined, the patient asked for an ampule of Coramine. He was found to be perspiring profusely. His skin was pallid, cold and wet. He was extremely weak and felt faint. He had a desire to move his bowels and passed a small semisolid fecal mass, which was guaiac negative. The pulse was 64, the blood pressure 100 systolic, 70 diastolic. One-sixth grain of morphine was administered. The patient remained pallid throughout the night. Early the next morning the blood pressure was 66 systolic, 30 diastolic, and the pulse below 70. His condition steadily improved in the next twelve hours.

An electrocardiogram on the day following admission showed a normal rhythm. The rate was 70. The PR interval was 0.2 second. The T waves were upright in Leads 1 and 2 and low in Lead 3. There was slight sagging of the ST segment in Leads 1 and 2. There was some evidence of left-axis deviation. In the chest leads, the QRS waves were normal and the T waves showed slight late inversion in CF₂ and were upright in CF₄ and CF₅.

The white-cell count was 6500, with 72 per cent neutrophils; the hemoglobin was 9.8 gm. There was moderate achromia, as well as variation in size and shape of the red blood cells; the platelets were diminished. The blood nonprotein nitrogen was 42 mg. per 100 cc. The urine was normal.

X-ray examination of the abdomen showed a large homogeneous soft-tissue mass extending from the epigastrium to the iliac crests, apparently displacing the transverse colon downward. The hepatic and splenic shadows were not identifiable. The left kidney shadow was clear; the right could not be visualized.

The patient was transfused with 500 cc. of blood, and an abdominal exploration was performed on the fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: I just asked Dr. C. Sidney Burwell what he thought about the electrocardiographic findings and he said that they were not very exciting. That is as far as he would go. Surgeons are not supposed to know how to interpret these readings. We have the interpretation made for us by the internists, so I shall accept Dr. Burwell's opinion.

*On leave of absence

May we see the x-ray films?

DR. MILFORD SCHULZ: This shadow represents the very large, upper abdominal mass. You can see the psoas contours through it, so that I suspect it does not arise in the retroperitoneal area. The kidneys are visible and not enlarged. I believe that this shadow up here is the spleen. If it is, it is not enlarged. The lateral film is somewhat thin and shows the mass to extend almost to the anterior abdominal wall. There are no areas of calcification. When one holds the film obliquely one can just make out the spine, in which there appears to be no erosion.

DR. ALLEN: We have, then, this well-preserved, hard-working physician, aged seventy-five, who gives an extraordinary story of possible trauma to some organ in the upper abdomen. When I first glanced at this protocol I thought this might be quite simple and that we were dealing with a large abdominal aneurysm—a not too uncommon finding in people who have arteriosclerosis. I note in the record that the aortic pulsations were transmitted vigorously through this tumor, but nothing is said about lateral expansion, and I have to assume that it was not expansile. Also, from the size of the mass alone I think that one could feel quite sure that this was not an abdominal aneurysm. I have never seen an aneurysm so large as this, provided that this whole shadow, which is larger than a dinner plate in diameter, is the mass that is described. Therefore, I think I shall have to assume that this was probably not an aneurysm.

What sort of mass could develop over a period of eight years, known to be present for at least three years by the patient himself, and from what organ could it arise? One immediately thinks of the possibility of a large pancreatic cyst, which would fit the location quite well and conceivably might coincide with the history of trauma. In the beginning of this story one might try to associate these periods of vasomotor collapse with some pancreatic disturbance. On the other hand the tumor is not consistent with the type of pancreatic tumor that ordinarily produces such marked and transient changes in the vascular bed.

There is the possibility that this tumor became acutely enlarged from hemorrhage following additional trauma. On at least three occasions when he worked too hard or strained or injured himself, acute episodes occurred. Pressure from sudden enlargement before nature could adjust the vasomotor system might explain the attacks of syncope. There is the possibility that these periods of faintness and sweating, certainly the one associated with a definite lowering of the blood pressure, were associated with this "nonexciting" elec-

trocardiogram. I am not competent to pass on that, but I should rather expect that they had nothing to do with any change in the heart or in the heart muscle.

Other tumors in this region must be considered. The roentgenologist kindly points out that one can see through the tumor wall, which suggests that it might be cystic. He also points out that the spleen has a normal shadow in its proper position. The location of the mass is against its being a tumor of the spleen or liver. It is fairly centrally placed, whereas one would expect it to be more lateral if it arose from either of these organs. Therefore, I think we cannot expect it to be a cyst of the spleen, liver or kidney, but we must consider the possibility of a mesenteric cyst. Mesenteric cysts are not frequent but they do occur. They are painless to palpation unlike lymphomatous masses, which are always tender to palpation. They do have a tendency to produce some digestive symptoms on occasion. A cyst of the gastrosplenic mesentery, for example, could perfectly well displace the colon downward. There is perhaps some shadow here of the colon, which suggests that it has been pushed downward. I do not particularly see why the colon should have been pushed down into the pelvis by a pancreatic cyst, although an attachment could have been effected, possibly from an inflammatory process.

That is about as far as I can go. Obviously this was not considered to be an aneurysm. I shall choose as my first diagnosis a mesenteric cyst, and as a second choice a pancreatic cyst.

DR. BENJAMIN CASTLEMAN: How do you account for the three episodes that he had?

DR. ALLEN: Lots of people have episodes of collapse and fainting from one cause or another that are not easily explained, particularly people in this age group. But I accounted for it on the basis of sudden increase in the size of the tumor from hemorrhage into it, owing to injury, overwork or strain. This might have produced an increase in size that was too difficult for the vasomotor or sympathetic system to adjust immediately.

DR. CASTLEMAN: Dr. Sweet operated on this patient with a preoperative diagnosis of cyst of the omentum. Perhaps he will tell us more about it.

DR. RICHARD H. SWEET: It is too bad they accepted the house officer's physical findings, because I was certain that it was not a cyst. The patient's own diagnosis was cyst of the mesentery. To me, the mass felt like a solid tumor, although I did not know where it came from. It could be moved from side to side, but not into the lower abdomen.

When it was placed over the aorta, it transmitted pulsations readily; when it was taken off the aorta, pulsations could not be obtained. Since it would

narrow pedicle but by a broad base measuring at least 20 cm. across and 5 to 7 cm. deep. Of course, the tumor was removed. The patient left the

FIGURE 1. *Photograph of the Tumor.*

not go into the lower abdomen, I knew it was attached to something higher up.

Another point of interest was that when the patient had this collapse in the hospital I called in a member of the staff who had seen him during two or three similar episodes at home. He thought the attack was cardiac in origin. He could not give it a satisfactory name, but thought perhaps that it was a vagal reflex or something like that.

At operation the cause of the collapse was manifested as soon as the abdomen was opened—he had bled into the abdominal cavity. There was a large amount of blood within the abdomen, and it was just old enough to have been associated with the attack of three days before. The tumor was obvious, and I saw immediately that the hemorrhage had come from a soft spot in the tumor. There was a tremendous blood supply from the omentum, which had become adherent to the upper surface of the tumor. The vessels from the omentum were enormous and very fragile, as omental vessels are when they are dilated. The tumor was solid, arising in the left lobe of the liver; it was attached not by a

hospital on the fifteenth postoperative day and perfectly all right at the present time (one month later).

CLINICAL DIAGNOSIS

Cyst of omentum.

DR. ALLEN'S DIAGNOSIS

Mesenteric cyst?

Pancreatic cyst?

ANATOMICAL DIAGNOSIS

Hepatoma.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The tumor measured about 10 cm. in diameter and was nodular. As Dr. Swann mentioned there was a necrotic focus on the surface, undoubtedly the source of the bleeding. The photograph (Fig. 1) is a cross section of the tumor showing that it is well circumscribed, with numerous yellowish-orange areas of necrosis, such as are not infrequently seen in renal-cell carcinomas. In fact, grossly, I thought that this pro-

bly was a metastasis from a renal-cell carcinoma. There was no evidence of cirrhosis in the surrounding liver tissue or of invasion of the hepatic veins—findings that are usually present in primary liver-cell cancer. Despite this, the tumor micro-

into the vena cava, metastasizing to the lungs. Dr. Schatzki* looked up a number of cases a few years ago and found that the average duration of life in the latter type is about six months.

DR. ALLEN: Was this in the right or left lobe?

FIGURE 2. Photomicrograph of the Tumor.

scopically is of liver-cell origin (Fig. 2), a very slowly growing hepatoma. We were unable to find any mitoses and classified it as a tumor of low-grade malignancy. Although the gross photograph shows that the tumor was completely encapsulated, a cross section at a deeper level revealed nodules of tumor in the liver parenchyma beyond the capsule. However, there was still a goodly margin of safety. When fixed in formalin, the tumor cells took on a greenish color, showing that they were forming bile.

It is interesting that this morning I was called to the operating room by Dr. Allen, who was operating on a girl with hemolytic jaundice. He removed the spleen and the gall bladder, which contained several gallstones, and then he found a nodule in the liver. He asked me whether he ought to resect it. I thought he should. We discussed the possibility of what it was, and he said that he thought it was a hepatoma.

DR. ALLEN: That is why it never occurred to me that this patient could have had a hepatoma.

DR. SWEET: Some of us have the impression that these tumors are usually very malignant. Is that so?

DR. CASTLEMAN: There are two types. The large solitary type can remain in the liver for years, with no untoward effects, and we occasionally find them incidentally at autopsy. Others are very malignant and spread via the hepatic veins

DR. SWEET: It was to the left of the falciform ligament. Grossly the remainder of the liver looked normal.

DR. ALLEN: Do you think that trauma had anything to do with the origin of this tumor?

DR. CASTLEMAN: No. I think that he had hemorrhage in the tumor because of the trauma.

DR. ALLEN: I mean at the time he was jostled in the automobile eight years before entry.

DR. CASTLEMAN: I believe that he already had the tumor at that time.

CASE 29332

PRESENTATION OF CASE

An eighty-nine-year-old physician entered the hospital because of change in mental state, aphasia and right-sided weakness of two days' duration.

The patient had been extremely active, busy and in apparent good health except for a dull "head" and occasional headaches during the previous year. Two days before admission he developed severe headache, unaffected by aspirin, and vomited several times. Vomiting was not projectile. On the afternoon of that day he fell on the way to the toilet, bruising his face. He was restless during the night, voided in bed and developed

*Schatzki, R. Roentgenological diagnosis of primary carcinoma of liver. *Am J Roentgenol* 46:476-483, 1941

weakness of the right arm as well as generalized weakness. He was unable to stand up without aid. The blood pressure was said to have been 90 systolic, 50 diastolic, on one occasion, and 138 systolic, 90 diastolic on another. For the two days preceding entry the family noted gradually increasing mental dullness. He was slow in response to questioning and experienced difficulty in expressing himself until the time of admission, when he was unable to talk although he seemed to comprehend what was said to him. The restlessness had also increased.

At the age of eighty-four he was in the hospital for three days with the diagnoses of slight congestive failure and partial auriculoventricular block, associated with coronary heart disease. About six weeks before entry he fell, striking his head, nose, eye and ribs. The injuries were minimal and recovery seemed complete, although later examination showed a depressed fracture of the nose. It was not known whether the patient had been unconscious at that time. He had headaches off and on since.

Physical examination showed a semistuporous and restless man. There was a fresh hematoma on the right outer orbit that had apparently developed since the fall in the bathroom. The eyes looked forward in spite of efforts to make him look in other directions. The chest was barrel shaped and moderately fixed in expiration. The lungs were clear. The heart sounds were distant and of poor quality but regular. A questionable late diastolic murmur was heard over the precordium. There was definite weakness of the right arm. The lower extremities were essentially normal. A positive Babinski sign was obtained on the left. The tendon reflexes were bilaterally equal. He was unable to speak but seemed to recognize his surroundings. The neck was not stiff.

The blood pressure was 110 systolic, 74 diastolic. The temperature was 99°F., the pulse 70, and the respirations 23.

Urine examination showed an alkaline reaction with a + test for albumin. The white-cell count was 9000. The blood Hinton test was negative.

The following day the patient could not be aroused. He developed marked Cheyne-Stokes respirations, with blood pressures of 135 systolic, 80 diastolic, during hyperpnea, and 100 systolic, 60 or less diastolic, during apnea. There was no cyanosis or edema but occasional hiccups. The weakness of the right face and the arm appeared to be progressing.

An electrocardiogram revealed marked sinus arrhythmia, with a rate of 100 to 50 but with rela-

tively normal P, Q, R, S and T waves; the P interval was 0.2 second.

During the next three or four days the patient condition remained essentially the same, with perhaps slight progressive improvement. On the fifth hospital day he had fewer hiccups and seemed to recognize his friends but was still unable to speak. The blood pressure varied from 140 systolic, 90 diastolic, to 110 systolic, 80 diastolic.

During the next seven days he seemed to alternate between periods of drowsiness and alertness. When alert, he answered questions intelligently, recognized his friends and family and wanted to get up. He was unable to move the right arm or leg. There were no apparent sensory disturbances and no hemianopsia. It was not known whether he had any headache. The blood pressure ranged from 110 systolic, 75 diastolic, to 116 systolic, 100 diastolic.

On the fifteenth hospital day the patient became unresponsive. Respirations were rapid, with rales at both bases but without dullness. The temperature, pulse and respirations increased, and there was cyanosis of the lips and tongue. During the next two days, the respirations rose to 40, and he died on the seventeenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. G. COLKET CANER: The chief points in this case are as follows: The patient had a head injury, followed by headaches off and on for six weeks, and then a severe headache, which either preceded or followed another head injury—the history is not clear which came first. This severe headache was associated with vomiting. He then had increasing difficulty in expressing himself but seemed to understand. He also developed weakness of the right arm and became less responsive and finally comatose. After four days he improved.

In regard to location, the weakness of the right arm and the motor aphasia point to the left frontal parietal region, cortical or subcortical, as that is the greatest brain damage. A lesion in this region would affect the left cortical center for conjugate deviation of the eyes and would result in inability to turn the eyes to the right. The fact that the eyes could not be turned to either side suggests bilateral lesions. Bilateral lesions would also explain the fact that he had weakness of the right arm and aphasia and also a Babinski response on the left. However, the Babinski on the left can also be explained by an expanding left-sided lesion that caused pressure on the left cerebral peduncle by the edge of the tentorium. The rather rapid development of coma suggests rapidly increasing intracranial pressure affecting the mid-

brain. The hiccups might have been due to mid-brain or medullary compression secondary to generalized increased intracranial pressure.

The age of the patient, together with the fairly rapid development of coma, suggests a vascular lesion and the history is rather typical for subdural hematoma. It is well known, of course, that subdural hematomas may follow minor head injuries, particularly if arteriosclerosis has diminished the elasticity of the blood vessels. It is well known, too, that a hematoma is frequently found on both sides of the brain, and as I have said, there is reason to suspect bilateral lesions in this case. A subdural hematoma would explain the intermittent headache for six weeks following the first head injury, and it would account for the severe headache and other symptoms whether or not they began before or after the second head injury. It would also explain the rapidly increasing coma without extension of the paresis. In fact I see nothing in the record that cannot be easily explained by this diagnosis. It seems to me that, with a history of this kind, burr holes are indicated. When a subdural hematoma is a possibility there is much more to be gained by this procedure than there is to lose.

The other possibilities are cerebral thrombosis, intracerebral hemorrhage, subarachnoid hemorrhage, and tumor with hemorrhage or acute edema around it.

I think thrombosis is the least likely because it does not explain the headaches for six weeks and because one would expect that a thrombosis large enough to cause coma would cause a hemiplegia and probably a hemianesthesia and hemianopsia, whereas the patient only had aphasia and weakness of the arm and face.

Intracerebral hemorrhage also seems unlikely. The onset would have been more rapid if there had been a hemorrhage. This is also true of subarachnoid hemorrhage, which, in addition, would probably have resulted in a stiff neck. The history seems much more suggestive of a vascular lesion than of tumor, although tumor with hemorrhage into it cannot be ruled out.

Finally, I see no relation between the patient's cerebral symptoms and the heart disease that necessitated hospitalization five years previously, except that arteriosclerosis was probably a factor in the development of the subdural hematoma and seems to have been the cause of the heart disease. I think an electroencephalogram would have been more useful than an electrocardiogram. My diagnosis, therefore, is subdural hematoma, probably bilateral, with general arteriosclerosis and terminal bronchopneumonia.

DR. HENRY R. VIETS: Was a lumbar puncture done?

DR. CHARLES S. KUBIK: No.

DR. VIETS: That might have thrown more light on the problem.

DR. KUBIK: Dr. Ayer, would you like to make any comment?

DR. JAMES B. AYER: It was thought best, because of the patient's eighty-nine years, to do as little as possible; so that even a lumbar puncture

FIGURE 1. Photograph of the Superior Surface of the Brain Showing Marked Depression on the Left and Slight Depression on the Right

was not done. Encephalograms were impractical. It was suggested that the lesion was a subdural hematoma and that possibility was held to. However, even if it was a subdural hematoma, it was thought that the patient would not stand operation and radical treatment was therefore not pushed. The improvement in the week before he died was so striking that thrombosis seemed more likely.

CLINICAL DIAGNOSIS

Cerebral thrombosis?
Subdural hematoma?

DR. CANER'S DIAGNOSES

Subdural hematoma, bilateral.
Generalized arteriosclerosis.
Bronchopneumonia, terminal.

ANATOMICAL DIAGNOSES

Subdural hematoma, bilateral.
 Calcific aortic stenosis.
 Cardiac hypertrophy.

PATHOLOGICAL DISCUSSION

DR. KUBIK: There were bilateral subdural hematomas, as Dr. Caner suspected. That on the left side was considerably larger, although the encapsulating, rather dense, fibrous membranes were of the same thickness and presumably of the same

the larger hematoma was situated (Figs. 1 and 2). Although a marked cerebellar pressure cone did not exist, there was a deep groove across the medulla where it rested against the anterior margin of the foramen magnum. Thus there was evidence of medullary compression, which presumably accounted for the respiratory difficulty.

DR. VIETS: Did the tentorium cut in enough to account for the positive Babinski sign on the left?

DR. KUBIK: Apparently not, although that is a fairly common occurrence with subdural hema-

FIGURE 2. Photograph of Cross Sections of the Cerebral Hemispheres Showing Marked Depression on the Left and Slight Depression on the Right.

age. Both hematomas consisted almost entirely of dark purplish-red fluid, which escaped when the dura was incised; there was little organized or unorganized blood clot. The spaces occupied by the hematomas were completely surrounded by fibrous membranes—an outer one that was adherent to but easily stripped from the inner surface of the dura, and an inner one that lay between the hematoma and the arachnoid membrane, to which it was not adherent. These encapsulating membranes are fibroblastic structures derived from the dura.

There was characteristic depression by the hematomas of the surfaces of the cerebral hemispheres, much more pronounced on the left side, where

toma; the midbrain may be displaced so far to the opposite side by a temporal pressure cone that the contralateral cerebral peduncle is forced against the margin of the tentorium. An actual groove across the peduncle may result. By implication of the corticospinal tract above its decussation, a homolateral hemiparesis or hemiplegia occurs. In this patient, the bilateral signs can probably be explained by the bilateral lesions.

DR. BENJAMIN CASTLEMAN: The heart was slightly hypertrophied, weighing 450 gm. This was apparently due to a marked calcific aortic stenosis. The coronary arteries showed a moderate degree of atherosclerosis but no appreciable narrowing.

UNITED STATES CADET NURSE CORPS

It is well known, particularly by physicians, that the war effort has created a serious shortage of nurses. During the current year, it is estimated that 65,000 new student nurses must be enrolled if the essential military and civilian nursing services are to be fully covered, and to assist in meeting this need, Congress has recently passed the Bolton Act, which creates the United States Cadet Nurse Corps.

In essence, the act provides for grants-in-aid to nursing schools whereby the student nurse is relieved of the burden of tuition and other fees and expenses that she would ordinarily

herself and, in addition, is paid a small monthly stipend. The student is permitted to enter the nursing school of her choice, provided that it is participating in the program and that she is able to meet its scholastic, personal and physical requirements. Furthermore, any student nurse who enrolled in a participating school subsequent to January 1, 1941, is eligible to join the corps. The cadet must agree, however, to engage in essential nursing—military or civilian—for the duration of the war. For the nursing schools, certain broad requirements are specified regarding minimum standards of nursing education and acceleration of the training program. Additional information concerning the new program is contained in a short article by Surgeon General Thomas Parran in the July 10 issue of the *Journal of the American Medical Association*, and details may be obtained from nursing schools, state nursing councils or associations and the Division of Nurse Education, United States Public Health Service, Washington, D. C. Recruitment of student nurses has encountered severe competition from the many opportunities available at present to high-school graduates, especially in the uniformed services and in war industry, where pay is immediate, and it is hoped that this legislation will aid in meeting the competition and will thus result in appreciable numbers of student nurses.

The family physician can do a great deal to support this worthy program. It is only natural that young women who contemplate joining the Cadet Nurse Corps should turn to him for advice and guidance. In pointing out to the prospective nurse some of the reasons why she is needed and how she will benefit herself and her country, the physician on the home front will make still another patriotic contribution to the prosecution of the war. Furthermore, it is to his own interest to stimulate recruitment, since, as his load of work becomes heavier, nurses can be of increasing assistance to him. In fact, all physicians are urged to utilize every means to encourage young women to accept this new opportunity to aid in meeting

THE FIRST COLLEGE TEXT IN OPTICS

THE long-delayed renaissance in medicine, which even lasted through the seventeenth century, is well illustrated by the first college text in optics, published in London in 1651. The author, Thomas Powell, a Welshman, was, it is true, not a physician but an erudite Doctor of Divinity at Oxford. His book, *Elementa Opticae Nova*, nevertheless, must have been widely read for only two copies seem to have survived, one in the British Museum, and the second recently acquired by the Dartmouth College Library. In his description of the Dartmouth copy, Burian* points out that Powell only compiled the opinions of the philosophers and poets of the Greco-Roman period, ignoring the writings of his own time. His anatomy of the eye is based entirely on Galen's description, the lens being placed in the center of the eyeball, although Fabricius ab Aquapendente had described it properly in 1600. Powell considered the lens as still the main receptor organ in the eye, in spite of the fact that Kepler and others had already considered its function as a purely dioptric one. The author also listed seven extraocular muscles, although in the sixteenth century Fallopius had correctly described six. Powell, therefore, did not go beyond Euclid and Ptolemy and depended heavily on Aristotle.

Thus science was delayed. The ophthalmologic student of 1651 in England had only this book to use, and thus his outlook was turned back at a time when Harvey and his few contemporaries were moving forward against the strong tide. However, the tide was ebbing, and before long Powell and his static science were to be finally overcome by Leeuwenhoek, Boerhaave, John Taylor and particularly William Porterfield and Thomas Young.

Powell, in his missionary zeal to keep the world clean, was disgusted with what he describes as "paradoxes and monstrous new opinions." He

could not stomach the "demented and eccentric ambition" to "attain a new Medicine, a new Philosophy." Men of his type, as pointed out by Burian, kept the teachings of men such as Kepler waiting for well over a century before they became the common property of even the men of science.

MEDICAL EPONYM

BESNIER-BOECK-SCHAUMANN DISEASE

On February 14, 1889, Dr. E. M. Besnier (1831-1909), physician of the *Hôpital Saint-Louis*, presented at a meeting of the physicians of that hospital a case of *lupus pernio de la face*. This case report appears in *Annales de dermatologie et de syphiligraphie* (Second Series, 10: 333-336, 1889). A portion of the translation follows:

A kind of erythematous lupus of the face in the form of erythema pernio or local asphyxia, for which I propose the designation lupus pernio, or asphyxial lupus, allied to Hutchinson's chilblain lupus, but not quite identical.

Ten years later, Caesar Peter Moeller-Boeck (1845-1917), professor of dermatology and syphilis at Oslo, published an article entitled "Multipelt benign hud-sarcoid [Multiple Benign Sarcoid of the Skin]," which appeared in *Norsk magasin for lægevidenskaben* (60: 1321-1334, 1899). After referring to clinical accounts of similar lesions, he concludes as follows:

The above described tumor, which so far as I know is here studied for the first time, at least histologically, thus seems clinically and histologically to occupy an independent position, and on the basis of the histologic findings I have ventured to designate it provisionally as "multiple benign sarcoid."

The possibility exists that further study may demonstrate it to be related to the pseudoleukemias.

Dr. Jörgen Schaumann, of Stockholm, published a paper "Etude sur le lupus pernio et ses rapports avec les sarcoides et la tuberculose [Study of Lupus Pernio and Its Relation to Sarcoids and Tuberculosis]" in *Annales de dermatologie et de syphiligraphie* (Fifth Series, 6: 357-373, 1917). Following a reference to Dr. Besnier's case, he concludes:

Lupus pernio and cutaneous sarcoids are symptoms of one and the same disease.

This disease is a tuberculoid lymphadenopathy characterized by the multiplicity of its lymphatic distribution in the lymph nodes, the tonsils, the bone marrow, the lungs, the spleen and the liver.

*Burian, Hermann M. A text for the times of Cromwell. *Dartmouth College Library Bulletin* 4 19 24, 1943.

WAR ACTIVITIES

FOOD RATIONING

The following statement, reprinted from the July 17 issue of the *Journal of the American Medical Association*, is a summary covering recent amendments in the regulations governing food rationing.

The Office of Price Administration announced on July 2 that any medical practitioner authorized by the state in which he practices to prescribe all internal drugs is also authorized to certify that a person requires supplementary food rations for health reasons. Authority to make such certification was previously confined to doctors of medicine. OPA has now broadened the authority so that osteopaths in states which license osteopaths to prescribe all internal drugs may also prescribe supplementary food rations. Food rationing regulations provide that a person whose health requires more rationed food than his ration points permit him to buy may apply to his local board for necessary additional points. In some instances foods are prescribed in addition to drugs or medicines or as a substitute for them. In some counties the work of ration boards in processing such applications has been much simplified through the voluntary help of the doctors themselves. By establishing panels to review all medical certifications and to advise the boards responsibility for issuing extra rations for health reasons has been kept on a professional level.

OPA, under date of June 1, placed evaporated and condensed milk on the list of rationed products. These types of milk are added to the group of rationed foods containing meats and fats, for which red ration stamps are needed without any increase in the total number of points allowed for this group. One point is required for one 14-ounce can or for two 6-ounce cans or for two 8-ounce cans. This means that the child may use 7 of his 16 points per week for his milk requirements in terms of evaporated milk which allows slightly less than the equivalent of a quart of whole milk per day and have 9 points remaining for his meat and fat requirements. An invalid or any other person whose health requires that he have more canned milk than he can obtain with the stamps in his ration book may apply at his local ration board for additional points. The consumer must submit a written statement of a licensed physician showing why he must have more canned milk, the amount needed during the succeeding two months and why unrationed foods cannot be used instead. A supplemental allotment to acquire canned evaporated and condensed milk needed by a hospital to meet the dietary needs of its patients may be obtained on application to its local ration board. It is understood that if the present method of rationing does not make evaporated milk available in all areas for infants and children, some more effective method will be worked out.

OPA has issued an amendment to Ration Order 16 (Amendment 25), which permits the use of rationed fats and oils for external therapeutic purposes. This includes the use of vegetable oils, such as cottonseed oil, for bathing newborn infants, for external application in skin diseases for urethral injection or lubrication of urethral instruments and for x-ray visualization. Such use of rationed fats and oils is defined as "industrial consumption" and persons using these products for such purposes are classified as "industrial consumers." An industrial consumer engaged in the care and treatment of the sick and needing rationed fats and oils for this purpose may apply to his district OPA office for a certificate with

which to acquire them. The procedure to be followed, briefly, is as follows. The application should be made on Form R 1605 to the district office. If the applicant is a hospital the district office will pass on the application by using the same method of computing allowances as the local boards use in computing allotments for industrial users, otherwise the application will be forwarded to the Washington office for action. If the applicant requires more than he would receive by the method of computation described he should also submit Form R 315 stating the reasons for such request. An industrial consumer to whom a certificate is issued for "industrial consumption" of rationed fats and oils may use it only to acquire the foods for which application was made and may use those foods only for the purpose for which the application was granted.

For several months OPA and medical authorities have been studying the hospital problem with a view to developing a uniform procedure covering the granting of supplemental allotments for hospitals. Solution of the problem is believed near. In the meantime a provision in the regulations (Ration Order 5, Section 116) should enable hospitals to obtain the necessary supplemental allotments so that patients need not suffer from dietary deficiency. This provision gives local boards authority to grant such allotments to meet the dietary requirements of patients living in and receiving care in hospitals whether or not such patients are on special diets. In determining the amount of the supplemental allotment for processed foods and the commodities covered by Ration Order 16, the local board will take into consideration the availability of fresh fruits and vegetables, unrationed substitutions, such as poultry and fresh fish, and the physical facilities of hospitals to process and store such foods.

NEW HAMPSHIRE MEDICAL SOCIETY

FRENCH—EDWARD H. FRENCH, M.D., of Wollaston, Massachusetts, died May 4. He was in his eighty-seventh year.

Dr. French graduated from Dartmouth Medical School in 1892. He was a member of the staff of the New Hampshire State Hospital from 1893 to 1896 and superintendent of the Medfield, Massachusetts State Hospital from 1896 to 1917. Dr. French, as a member of the New Hampshire Medical Society, received a gold medal in recognition of his fifty years of membership in 1935.

MISCELLANY

THE FAMILY DOCTOR, THE PATIENT AND THE JOB

The first step in the rehabilitation of a tuberculous person is physical restoration, which is particularly the province of the physician. In the further adjustment of the inactive patient the lay worker who attempts to serve the patient without learning the story of diagnosis, treatment and recovery from the physician, treads on quicksand. Most successful rehabilitation follows the concerted application of the medical skill of the physician and the special information and training of qualified lay workers. Practical suggestions for the family physician who is interested in such co-ordination are here presented by Dr. F. L. Jennings, superintendent and director of the Sunnyside Sanatorium, Indianapolis, Indiana.

The private physician who has guided his patient through recovery from pulmonary tuberculosis is now

being asked frequently to advise concerning some job which that patient may attempt without too great hazard. In this general manpower shortage, the patient with inactive tuberculosis, whether from civilian life, from induction centers or discharged from military services, can find employment readily in many localities, particularly if he has an established skill. Besides that economic need which makes many patients reluctant to continue treatment for the prescribed period, patients now are moved by the wish to become a part of the war effort and sometimes by high wages. Some employers who hire all comers are unlikely to establish any safeguards for handicapped workers.

One of the physician's paramount difficulties has been the item of sufficiently definite information about the job in question. Jobs are changing rapidly. The exhausting task of a year ago has been reduced to machine-tending. Redesign, retooling, reorganization and re-routing continue to make more specifications obsolete. Keeping up with such rapid and drastic change is impossible alike for any physician or lay worker without current sources of industrial information. Some physicians have sought to bridge this difficulty by such general terms as "light work," hoping thereby to protect the patient from excessive exertion, strain and tension. Unfortunately, employers' requirements are definite. Employment placement interviewers must meet these definite requirements. A patient's ability to do "light work" is indefinite and unsalable.

But there are now official and unofficial sources of information through which physician and patient may usually find definite indications concerning which job is free from undesirable hazards. The official services include the United States Employment Service, which has branch offices in most population centers, and the state vocational rehabilitation services. The United States Employment Service has the most complete and currently accurate information on what jobs there are in each community and on what physical performance is required in each job. It has originated a "Physical Demands Form," which is being used experimentally to determine required physical activity and working conditions. This type of job analysis explores especially such items as continuous standing, sitting, lifting, stooping and so forth. One purpose of this information is to check the specific requirements of the job against the specific limitations of the handicapped applicant.

Interested physicians may obtain copies of interim physical requirement forms from the National Tuberculosis Association. The larger offices of the United States Employment Service also include executives or interviewers who have some experience in special placements and who are qualified to discuss the subject of suitable placement for recovered patients with their physicians. The service has placed thousands of inactive tuberculous patients in hundreds of different jobs. The suitability of these placements has depended most of the time on the quality and quantity of medical information available.

When the recovered tuberculous patient has no marketable skill, or when his old job is contraindicated medically, application for training or retraining and placement should be made to the state bureaus of vocational rehabilitation. Financed by state appropriations and federal matching funds, these bureaus are empowered to impart specific vocational training and placement to handicapped adults in order to make them self supporting.

The physician will find in Federal Form R-3a (revised), published by the Federal Vocational Rehabilitation Bu-

reau and in the manual prepared for its interpretation (Misc. 2328) practical bases on which rehabilitation agent and physician may cohere their services for the patient. The form and the manual are the result of many consultations between federal rehabilitation personnel and members of the Council of the American Trudeau Society and other phthisiologists of long experience. Many state agents and supervisors have learned that, as the federal manual points out, direct interview between physician and rehabilitation worker is the most satisfactory procedure for both.

A number of the state and local tuberculosis associations have included rehabilitation in their program objectives. Some have employed special personnel competent to assist the patient in finding his way to appropriate training or placement or both. Rehabilitation workers employed by voluntary agencies are well aware that the patients of private physicians may have as much need for their services as the sanatorium graduate. The physician may find it well worth while to inquire from the nearest tuberculosis association what it has to offer in the direction of rehabilitation.

Both official and voluntary resources have been stimulated and encouraged by changing attitudes within industry. Not manpower shortage alone, but a cumulation of satisfactory performance by former patients, has done much to improve this situation.

The nation's leading personnel agency, the United States Civil Service Commission, has conducted surveys of jobs in several types of federal services and in war-contract industries in search of jobs suitable for physically handicapped persons. Prospective employment for persons with a history of tuberculosis has been conspicuously included.

This precedent has been matched by action on the part of the National Association of Manufacturers. In the December, 1942, supplement of its *Industrial Relations Bulletin*, the association indicated that various handicapped groups are a new labor source. Specific mention is made of employees who have suffered amputations, deafness, blindness, organic heart disease and tuberculosis. For each group, a partial list of suggested jobs is offered. The bulletin indicates that one of the parallel practices in employing handicapped workers calls for "careful selectivity in applying the handicapped man to a job which he can do." Again the private physician and the industrial doctor are able to provide medical advice and counsel. A number of large employers have recently utilized the specific job-analysis method developed by the United States Employment Service, described above.

Tuberculosis literature is not without its contributions on rehabilitation information of value to the physician. The *American Review of Tuberculosis* has in preparation articles prepared by the United States Employment Service and the Federal Vocational Rehabilitation Bureau regarding their procedures in cases eligible for their services. The Rehabilitation Service of the National Tuberculosis Association is preparing special releases on the subject of patients not eligible for official services. Thus, the physician, when called on to advise his patient occupationally, may utilize the services and the publications of the United States Employment Service, the rehabilitation bureaus and the tuberculosis associations to good advantage.—Reprinted from *Tuberculosis Abstracts* (August, 1943).

THE EFFECT OF VITAMIN K₁ OXIDE ON HYPOPROTHROMBINEMIA INDUCED BY DICOUMAROL*

CHARLES S. DAVIDSON, M.D.,† AND HARRIET MACDONALD, B.S.‡

BOSTON

MUCH attention has recently been given to the use of dicoumarol as an anticoagulant. The advantages of the drug over heparin, such as oral activity and relatively low cost, are apparent, but the serious disadvantage of lack of control has been given less attention.¹ Overman et al.² point out that in rats vitamin K has an action antagonistic to that of dicoumarol. Shapiro et al.³ gave small doses of dicoumarol to patients and found that the combined oral and parenteral administration of large amounts of 2-methyl-1,4-naphthoquinone—a synthetic compound similar to vitamin K—prevented the prolongation of the prothrombin time following the administration of dicoumarol.

It seemed advisable to determine whether vitamin K has any influence on the action of dicoumarol given in therapeutic doses. It was evident that very large doses of the vitamin would be required because usual doses, or even those ordinarily thought to be large, have been shown repeatedly to be ineffective.⁴⁻⁷ An occasional report concerning the control of large doses of dicoumarol by vitamin K has appeared in the literature.⁸

Fieser⁹ and Seligman et al.¹⁰ have pointed out that the synthetic compound 2-methyl-1,4-naphthoquinone differs greatly, both chemically and physiologically, from true vitamin K₁ or K₂. Furthermore, it is known that this compound has produced toxic effects in small animals.¹¹ Therefore it seemed inadvisable to administer large doses to patients.

True vitamin K₁ oxide,§ synthesized by the

§The vitamin K₁ oxide was kindly supplied by Dr. Arnold Seligman, of the Peth Israel Hospital, Boston, and by Merck and Company, Rahway, New Jersey.

method of Fieser¹² and prepared for use as suggested by Davis et al.¹³ was employed in this investigation. The amount of vitamin K₁ oxide was accurately measured either volumetrically or by weighing. The latter method is probably more accurate. From 100 to 450 mg. of vitamin K₁ oxide in oil form was dissolved in 15 to 20 cc. of absolute alcohol. The resulting solution was poured slowly, with sterile precautions and constant agitation, beneath the surface of 1000 to 1500 cc. of 5 or 10 per cent glucose in water. A fine suspension of the vitamin was thus obtained. The patients received by intravenous administration 1000 to 1500 cc. of this preparation. The time of administration varied from three to five hours. No serious untoward effects were noted. Two patients complained of headache and 1 vomited following the injection. The amount of alcohol administered produced no untoward effect except the production of a mild euphoria in some patients.

The dicoumarol|| was used in the form of the crystalline compound and administered orally in gelatin capsules.

The prothrombin times were determined by a modification¹⁴ of the method of Quick.¹⁵

RESULTS

The effect of the administration of vitamin K₁ oxide on the hypoprothrombinemia produced by dicoumarol was studied in 5 patients. Two methods of attack were used. In one an attempt was made to prevent dicoumarol from having its customary hypoprothrombinemic effect. In the other the full effect of dicoumarol was permitted to occur and vitamin K₁ oxide was then administered in an attempt to bring the prothrombin concentration back to normal.

Figure 1 demonstrates the preventive action of 180 mg. of vitamin K₁ oxide on the effect of di-

||The dicoumarol was kindly supplied by the Abbott Laboratories, North Chicago, Illinois.

coumarol administered orally in a dose of 500 mg. Following the administration of the dicoumarol, the patient's prothrombin time rose from a normal value of twenty-eight seconds to a maximum of fifty seconds two days after the administration of the drug. Twelve days later a second dose of 500 mg. of dicoumarol was administered. Five hours later the intravenous injection of vitamin K₁ oxide was commenced and 180 mg. was administered in the next two hours. As shown in the figure there was no significant change in the prothrombin time of this patient when the vitamin K₁ oxide and dicoumarol were administered in the doses and under the conditions described above. After a lapse of twelve days, a third dose of 500 mg. of dicoumarol was administered without the simultaneous administration of vitamin K₁ oxide.

FIGURE 1. *The Preventive Action of Vitamin K₁ Oxide on the Hypoprothrombinemia Induced by Dicoumarol.*

The response to the dicoumarol was prompt and the usual hypoprothrombinemia resulted. It should be noted that following the first administration of dicoumarol five days elapsed before the prothrombin level returned to normal, and following the third administration a period of eight days was required to obtain this result.

Figure 2 demonstrates the effect of the administration of vitamin K₁ oxide on the hypoprothrombinemia obtained following the administration of dicoumarol. In this patient 500 mg. of dicoumarol was insufficient to produce a marked hypoprothrombinemia, and a second dose of 1 gm. of the drug was therefore administered three days later. The prothrombin time rose from a normal value of 25 seconds to 55 seconds in a period of two days. At that time, 250 mg. of vitamin K₁ oxide was administered intravenously. A prompt reduction in the prothrombin time occurred. In four hours it fell to 35 seconds, and in twelve hours to 31 seconds, and in twenty-four hours it returned to its original normal value. Four days after the prothrombin time was normal, a second dose of 1 gm. of dicoumarol was administered,

with a consequent rise in prothrombin time from 25 seconds to 75 seconds over a period of two and a half days. However, six and a half days elapsed before the prothrombin time returned to normal, in sharp contrast to the rapid reversal of the hypoprothrombinemia observed when vitamin K₁ oxide was administered. This important difference in rate of return is demonstrated more

FIGURE 2. *The Antagonistic Action of Vitamin K₁ Oxide on Dicoumarol.*

clearly in Figure 3, in which the fall of the prolonged prothrombin time produced by dicoumarol, with and without the administration of vitamin K₁ oxide, is plotted in hours.

Three other patients were studied with respect to the action of vitamin K₁ oxide after the hypoprothrombinemia from dicoumarol had been established. The dose of dicoumarol used varied from 500 mg. to 1 gm. In 2 patients vitamin K₁ oxide was administered in a dosage of 350 and 450 mg., respectively, in two doses. In one of these

FIGURE 3. *The Effect of Vitamin K₁ Oxide on the Hypoprothrombinemia Induced by Dicoumarol.*
This is a portion of the curve shown in Figure 2, with the readings plotted in hours instead of days.

patients the prothrombin concentration returned to normal in fourteen hours, and in the other in twenty-four hours. The third patient was given

200 mg. of vitamin K₁ oxide after the hypoprothrombinemia had been established, without significant effect. Unfortunately, it was impossible to make further studies on this patient, but probably the dose administered was too small.

DISCUSSION

In 4 of 5 patients studied, the administration of vitamin K₁ oxide in large doses either prevented or reversed the hypoprothrombinemia produced by suitable doses of dicoumarol. Just as with the anticoagulant effect of dicoumarol, the amount of vitamin K₁ oxide required to produce an antagonistic effect varies from patient to patient and repeated doses of the vitamin may be necessary to secure the desired result. The quantitative relation between dicoumarol and vitamin K₁ oxide requires further study. Furthermore, it should be noted that the effect of vitamin K₁ oxide presented in this paper is confined exclusively to its effect on the hypoprothrombinemia produced by a single dose of dicoumarol. It will be necessary, therefore, to establish the usefulness of the vitamin as a means of controlling the coagulation time in patients who are receiving a prolonged course of dicoumarol. If, under these circumstances, it can be established that vitamin K₁ oxide acts in a similar fashion to that obtaining for a single dose of dicoumarol, it would seem likely that many of the dangers following the use of this anticoagulant can be removed.

SUMMARY AND CONCLUSIONS

The activity of large doses of vitamin K₁ oxide in reversing the hypoprothrombinemia produced by dicoumarol has been demonstrated in 3 out of 4 patients studied. It is probable that an inadequate amount of the vitamin was administered to the fourth patient.

In 1 patient, the administration of vitamin K₁ oxide prevented the subsequent establishment of a hypoprothrombinemia following the administration of dicoumarol.

The amount of vitamin K₁ oxide required to produce the desired effect varied considerably from patient to patient.

No serious toxic manifestations were observed from the administration of large amounts of vitamin K₁ oxide. The only untoward action observed in this small series of patients was transient headache and, in 1 patient, vomiting.

It is suggested that the action of vitamin K₁ oxide in reversing the hypoprothrombinemia established by single doses of dicoumarol may make the therapeutic use of this anticoagulant safer than it has heretofore been.

CARDIAC ARRHYTHMIAS FOLLOWING PNEUMONECTOMY*

C. CABELL BAILEY, M.D.,† AND REEVE H. BETTS, M.D.‡

BOSTON

AURICULAR flutter and auricular fibrillation may occur as functional disturbances in cases in which no definite evidence of heart disease is present.¹⁻¹⁴ Ritchie² and others^{3, 4} as early as 1914 observed that flutter sometimes occurred when there was no evidence of heart disease. Parkinson and Bedford⁵ reviewed 52 cases of flutter and discovered 5 patients who had no detectable heart disease. Orgain, Wolff and White,¹ in reviewing 5000 cardiac consultation cases, found that 36 (6 per cent) of 583 cases of fibrillation and 5 (14 per cent) of 38 cases of flutter occurred when no detectable heart disease was present. This indicates the rarity of these two conditions, especially functional auricular flutter. The purpose of this paper is to emphasize the relative frequency of cardiac arrhythmias, especially functional auricular fibrillation and flutter, following pulmonary resection.

In a series of 78 patients on whom total pneumonectomy was performed at the New England Deaconess Hospital, 4 cases of auricular fibrillation, 2 cases of auricular flutter, 1 case of flutter-fibrillation and 1 case of nodal tachycardia were encountered postoperatively. An additional case of auricular fibrillation was observed following a right middle and lower lobectomy. The right lung was removed in 3 cases, and the left lung in 6 cases. The patients' ages varied from thirty-two to sixty-six years. There were 6 males and 3 females. No history of rheumatic fever or syphilis was elicited. All patients except one (Case 4) had negative blood Hinton tests. One had a slight elevation of the systolic blood pressure (160 mm.), which later dropped to normal.

X-ray films taken at six feet revealed cardiothoracic ratios well below 50 per cent in all cases. Five patients had normal preoperative electrocardiograms. Careful history-taking and physical examination failed to reveal evidence of heart disease in any case before operation.

The arrhythmias appeared on the second, third (2 cases), fifth, seventh, fourteenth and fifteenth days following pneumonectomy. In Case 6, flutter followed left pneumonectomy by twenty-nine days and pericardiostomy for a sterile pericarditis

by only one day. In Case 9, fibrillation followed pneumonectomy by fifty-seven days and thoracoplasty by ten days. That the procedures mentioned precipitated the arrhythmia in Cases 6 and 9 is probable. In 8 cases normal sinus rhythm was restored within forty-eight hours by rapid digitalization. In Case 7 there were two transient attacks of auricular fibrillation; one ceased spontaneously, and the other thirty minutes after a test dose of 3 gr. of quinidine sulfate. The duration of the arrhythmias in 7 cases was between thirty and forty-eight hours. The remaining 2 cases, both of fibrillation, lasted two and ten hours, respectively.

A follow-up of these 9 cases in December, 1942, varying from eight months to five years after the arrhythmia, revealed that no patient had developed cardiac decompensation or had had a return of the cardiac arrhythmia.

CASE REPORTS

CASE 1. T. K., a 45-year-old housewife, was admitted on December 29, 1936, complaining of chronic cough for 4 years and occasional blood-streaked sputum for 2 years. In 1934 she had a paroxysm of tachycardia of 2 hours' duration. In November, 1936, bronchoscopy and biopsy showed carcinoma in the left main-stem bronchus. Pneumothorax was given.

Physical examination was negative except for left pneumothorax and slight clubbing of the fingers. The usual laboratory findings were negative except for a white-cell count of 22,950. X-ray study showed a left pneumothorax with atelectasis of the left upper lobe. The cardiothoracic ratio was less than 50 per cent. An electrocardiogram was normal except for a tachycardia of 108.

On January 5, 1937, a one-stage left pneumonectomy was done. The course was satisfactory until the 19th postoperative day, when the pulse suddenly rose to 172. It was regular and not changed by carotid or ocular pressure. The patient was conscious of the tachycardia but was not distressed. An electrocardiogram showed a nodal tachycardia with a ventricular rate of 170. Eighteen grains of digitalis was given in the first 24 hours, the first 3 gr. intramuscularly and the rest by mouth. Thereafter 1½ gr. was given daily until February 5, when the digitalis was discontinued. The pulse remained rapid and regular for 48 hours, when it returned to a normal rhythm at 110. An electrocardiogram showed a normal sinus rhythm with a rate of 116.

When examined 4 years after the operation, she stated that she had been free from symptoms except for a moderate pulmonary hemorrhage 1 year previously.

CASE 2. S. S., a 43-year-old Syrian saleswoman, was first seen on March 14, 1938, complaining of intermittent hemoptysis for 1 year and an almost continuous vague discomfort in the left lower anterior chest for 11 months. The latter was not related to exercise or excitement.

*From the George F. Baker Clinic and the Thoracic Surgical Service, New England Deaconess Hospital.

Read, in part, before the New England Heart Association, Boston, on January 18, 1943.

†Research fellow, Harvard Medical School; physician, New England Deaconess Hospital.

‡Surgeon, New England Deaconess Hospital (on leave of absence).

The only abnormality in the physical examination was diminished breath sound in the left axilla. Routine laboratory tests were negative. X-ray study showed atelectasis in the lower part of the left upper lobe. The cardiothoracic ratio was less than 50 per cent. A bronchogram showed obstruction of the lingular branch of the left upper lobe bronchus. Preoperative pneumothorax was then begun.

On April 11, a left total pneumonectomy was performed, two 500-cc. blood transfusions being given. The pathological report was adenocarcinoma of the left upper lobe. The patient did well until the 7th postoperative day, when she developed a sudden tachycardia of 170. She perspired and the skin felt clammy, but there were no other symptoms. An electrocardiogram showed auricular fibrillation, with a ventricular rate of 150. Twelve grains of digitalis was given in the first 12 hours and $1\frac{1}{2}$ gr a day thereafter for 10 days. Thirty-six hours after the onset of tachycardia the pulse returned to normal. The patient has been symptom free since then.

CASE 3 S K., a 55-year-old Russian merchant, was first seen on November 24, 1940, complaining of pain in the right chest and down the right arm for 5½ months. The physical examination and laboratory examinations were negative except for signs suggestive of atelectasis of the right upper lobe and moderate wasting of the small muscles of the right hand. X-ray examination showed a normal cardiac shadow with a cardiothoracic ratio of 39 per cent and atelectasis of the right upper lobe. Bronchoscopy revealed a mass protruding from the right upper lobe bronchus, subsequently proved to be carcinoma.

On December 13, after a preparatory right pneumothorax, exploratory thoracotomy was performed, which showed mediastinal metastases. Palliative pneumonectomy was done three 500-cc blood transfusions being given. Except for a transient atelectasis of the left upper lobe that necessitated bronchoscopic aspiration on the 3rd day the course was satisfactory until the 5th postoperative day, when the pulse suddenly rose to 170. Although the patient had no complaints slight sweating was noticed. An electrocardiogram showed auricular flutter fibrillation. Twenty-four grains of digitalis was given in the first 24 hours and $1\frac{1}{2}$ gr daily thereafter. After 20 hours the pulse dropped to 84 but again became rapid after ½ hour. Normal rhythm returned permanently 48 hours after onset. An electrocardiogram was normal except for slightly lowered amplitude of the QRS complexes. One week later, an electrocardiogram showed wide, slurred QRS complexes with depressed ST segments in all leads. The PR interval was 0.13 second. The digitalis was discontinued, and subsequently the ST segments and QRS waves returned to normal. The patient was discharged symptom free 47 days after operation.

Three months later an electrocardiogram was normal. Death from metastatic carcinoma occurred 11 months after discharge.

CASE 4 C Y., a 66-year-old Chinese bricklayer, was admitted on January 11, 1941, complaining of cough for 5 years and occasional hemoptysis for 2 years.

Physical examination was negative except for dullness and diminished breath sounds anteriorly and posteriorly over the lower half of the right lung and a few crepitant rales at the right base. The usual laboratory findings were negative except that the blood Hinton test was

repeatedly positive. The electrocardiogram was essentially normal. X-ray examination showed a shadow suggestive of atelectasis of the right upper lobe. The cardiac shadow was of normal size and the cardiothoracic ratio was 43 per cent. Bronchoscopy and biopsy showed epidermoid carcinoma in the right lower lobe bronchus.

Following pneumothorax an exploratory thoracotomy revealed that the mediastinum was invaded by the growth. A palliative right middle and lower lobectomy was performed during which two 500-cc blood transfusions were given. On the 2nd postoperative day the pulse suddenly rose to 190 and became irregular. The electrocardiogram showed auricular fibrillation. Fifteen grains of digitalis was given in the first 12 hours, $16\frac{1}{2}$ gr in the first 24 hours, and $1\frac{1}{2}$ gr daily thereafter. Normal cardiac rhythm returned after 48 hours. There were no further cardiac symptoms.

The patient died of metastatic carcinoma 6 months after operation.

CASE 5 N W., a 55-year-old retired manufacturer, was admitted on January 23, 1941, complaining of a slight cough for 1½ years and occasional vomiting for 1 year. He had lost 45 pounds. He took large quantities of alcohol.

Physical examination was negative except for a blood pressure of 160/88, a few crackling rales in the left midchest posteriorly and transient moist rales at the right base. The usual laboratory tests were negative except for a red cell count of 3,540,000, many red cells in the urine and a urinary albumin was 0.1 per cent. A diagnosis of idiopathic hematuria was made after thorough study, including intravenous and retrograde pyelograms. An electrocardiogram was within normal limits except for evidence of slight right axis deviation. X-ray study showed a normal cardiac shadow, with a cardiothoracic ratio of 40 per cent and an infiltration in the region of the left hilum suggesting neoplasm.

On February 3, after a preliminary left pneumothorax a one-stage left pneumonectomy was carried out, three 500-cc blood transfusions being given. The left vagus nerve was found imbedded in the tumor mass and was resected. Convalescence was satisfactory until the 3rd postoperative day, when the pulse suddenly rose to 165 and became irregular. An electrocardiogram showed auricular fibrillation. Twenty-four grains of digitalis was given in the first 24 hours and $1\frac{1}{2}$ gr daily thereafter. Normal rhythm confirmed by electrocardiogram, returned after 48 hours.

The patient was well when examined in January, 1942. An electrocardiogram at that time was normal except for evidence of slight left axis deviation.

CASE 6 R R., a 34-year-old clerk, entered the hospital January 28, 1941, complaining of an intermittent cough for 6 years. In 1937, bronchoscopy and biopsy had shown a benign adenoma in the left main stem bronchus. Deep x-ray treatments and intrabronchial radon were given. The cough and sputum decreased but slight occasional hemoptysis continued. There had been dyspnea on exertion for several years but no edema, orthopnea or palpitation had been present.

Physical examination was negative except that the left chest was limited in motion and there were dullness, harsh breath sounds and many rales over the lower half of the left lung field. The usual laboratory findings were negative. The Decholin circulation times from arm to tongue were 150 and 144 seconds. Filter circulation

times from arm to lung were 7.8 and 6.0 seconds. The venous pressure was 86 mm. of water. The vital capacity was 2380 cc. A preoperative electrocardiogram was normal. X-ray study showed atelectasis of the left lower lobe and a large emphysematous cyst of the left upper lobe. The mediastinum was deviated to the left. The exact cardiac thoracic ratio could not be obtained owing to marked displacement, but the heart appeared to be of normal size. Bronchoscopy and bronchography showed marked saccular bronchiectasis of the entire left lung.

On February 11, a left pneumonectomy, with four 500-cc. blood transfusions, was carried out. The course was satisfactory until the 19th postoperative day, when the patient developed a sharp substernal pain not related to respiration. The temperature rose to 102°F. every afternoon and a moderately loud pericardial friction rub appeared. For the next 9 days the patient became progressively worse. The liver increased in size and became tender. An electrocardiogram showed low QRS complexes and low T waves. The venous pressure rose to 200 mm. of saline solution on the 27th postoperative day. A diagnosis of pericarditis with effusion was made, and on March 11, the 28th postoperative day, the pericardium was explored and found to be approximately 0.5 cm. in thickness and shaggy. A loculated collection of approximately 100 cc. of clear fluid was found. The culture was sterile. The following evening the pulse was 170 but regular. An electrocardiogram showed auricular flutter. Twenty-four grains of digitalis was given in the first 24 hours and 1½ gr. daily thereafter. Normal rhythm, confirmed by electrocardiogram, returned in 30 hours. The liver size returned to normal, the abdominal discomfort disappeared, and there was no more chest pain. Improvement was steady. The patient was discharged on August 22.

There had been no more cardiac symptoms when the patient was examined 1 year later.

CASE 7. J. B., a 49-year-old clerk, was admitted on June 15, 1941, complaining of cough and soreness of the right chest for 7 months and blood-streaked sputum for 5 months. A bronchoscopic examination and biopsy on May 23 had shown epidermoid carcinoma of the right main-stem bronchus.

Physical examination was negative except for slightly impaired resonance over the right apex above the level of the 3rd rib anteriorly. The usual laboratory tests were normal. The Decholin circulation time from left arm to tongue was 19 seconds. A preoperative electrocardiogram was normal with the exception of R₄, which was only 1 mm. high. The cardiothoracic ratio at x-ray examination was 44 per cent.

On June 19, following a preliminary pneumothorax, a one-stage right pneumonectomy, with three 500-cc. blood transfusions, was done. The course was satisfactory until the 3rd postoperative day, when a rapid, irregular pulse was first noticed. An electrocardiogram showed auricular fibrillation with a ventricular rate of 160. Less than 2 hours later normal rhythm spontaneously returned. An electrocardiogram was normal, R₄ being 4 mm. high. The pulse remained regular and between 84 and 98 until the 6th postoperative day, when the patient was awakened by a "fluttering" in the chest and the pulse rate was found to be rapid and irregular. He was given 3 gr. of quinidine sulfate as a test dose. Thirty minutes later the pulse had returned to a normal rhythm of 86.

When seen 3 months later the patient was free of cardiac symptoms.

CASE 8. A. M., a 48-year-old man, was admitted on April 7, 1942, complaining of cough with occasional blood-streaked sputum of 1 year's duration, with a loss of 10 pounds in weight.

Physical examination was negative except for dullness with absent breath sounds over the left upper lung field. The usual laboratory findings were negative except for a red-cell count of 3,860,000 and a white-cell count of 19,900. X-ray study showed consolidation of the upper third of the left lung. The heart appeared normal. The cardiothoracic ratio was well below 50 per cent but could not be measured accurately. A diagnosis of pulmonary abscess was made.

On April 16, following preliminary left artificial pneumothorax, a total left pneumonectomy was performed, three blood transfusions being given. The left phrenic nerve was intentionally crushed. The course was satisfactory until the 15th postoperative day, when a regular pulse of 186 developed. The patient was unaware of the tachycardia. An electrocardiogram showed auricular flutter with a ventricular rate of 170 and an auricular rate of 340. Sixteen and a half grains of digitalis was given in 24 hours. The pulse at the end of that time was 166. During the next 14 hours he received 6 gr. of digitalis. The flutter lasted for 36 hours. On May 3 an electrocardiogram showed a regular sinus rhythm with a rate of 126. An electrocardiogram on May 5 showed sinus tachycardia, with a rate of 132, and one on May 21 showed sinus rhythm with a rate of 118.

There were no further cardiac symptoms.

CASE 9. A. R., a 32-year-old woman, was admitted on April 6, 1942, with a 6-year history of pulmonary tuberculosis limited to the left lung. She had had extrasystole for many years. On February 19, a left pneumonectomy had been done. The postoperative course was satisfactory and the patient was discharged on March 18. She was readmitted for thoracoplasty.

Physical examination was negative except for the lung findings. The usual laboratory examinations were negative. X-ray study showed a clear right lung but pneumothorax on the left. The cardiothoracic ratio was well below 50 per cent but could not be measured accurately.

On April 8, a left thoracoplasty was performed. The course was satisfactory until the 10th postoperative day (8 weeks after the pneumonectomy), when the patient vomited three times without obvious cause and immediately afterward developed a rapid, irregular pulse of 160 to 170. An electrocardiogram showed auricular fibrillation. One and a half grains of digitalis was given intramuscularly, followed by 7½ gr. orally during the next 10 hours. At that time normal rhythm returned for 1 hour, followed by a return of the rapid and irregular rate for 10 minutes. Thereafter the normal rhythm was permanent. Two days later an electrocardiogram was normal.

DISCUSSION

Attempts have been made to discover the cause or precipitating factors that initiate these arrhythmias. The fact that arrhythmia occurred in 8 of 78 cases following pneumonectomy, an incidence of nearly 10 per cent, whereas none occurred in 63 cases following single lobectomy, suggests that the more extensive procedure is essential

to its production. With total pneumonectomy there has been a decided shift in the mediastinum away from the affected side, and later in every case a pleural effusion has developed that required frequent thoracentesis. Although difficult to prove, this shift in the mediastinum may play a part in initiating these abnormal rhythms.

Following closure of the bronchus with silk mattress sutures after pneumonectomy, the vagus nerve on that side naturally falls in close apposition to the closed bronchus, if not actually in contact with it. Therefore infection of the bronchial stump or a stitch abscess in this area would be apt to irritate the vagus nerve. One indication of such an infection may be a rise in temperature. The case records were examined with this in view, and it was found that 2 cases showed a moderate rise in fever at the time the arrhythmia began. One of these patients had been afebrile for one week, when the fever rose to 101°F. without detectable cause. On the third day of fever the arrhythmia began. In 4 cases there was a slight but definite rise in temperature on the day of onset of the arrhythmia. Another patient had a continued temperature after operation, and on the seventh day of fever the tachycardia began. In 1 case the arrhythmia began the day after surgery, when fever is normally present, and hence could not be considered from this point of view. Only 1 patient remained afebrile at the time of the arrhythmia. If this hypothesis is correct, it would explain the variable latent period that follows the operation before onset of the arrhythmia, since the time of onset of the stitch abscess may vary. That vagal stimulation may induce fibrillation under certain conditions has been reported by several workers.¹⁵⁻¹⁸

One might consider further that the mediastinal shift acts like thyroxin or the faradic current and represents the E factor of Nahum and Hoff,¹⁶ and that the E factor combines with vagal stimulation, as suggested by these workers, to induce the arrhythmias.

Sulfathiazole powder was introduced into the chest cavity in 5 cases and sulfanilamide powder in 2 cases. No sulfonamide drug was used in 2 cases. Five patients received sulfathiazole orally after operation, whereas 4 received none. All operations were done under intratracheal cyclopropane anes-

thesia. It seems unlikely that any of these drugs were related to the arrhythmia.

SUMMARY AND CONCLUSIONS

Functional cardiac arrhythmias, especially auricular fibrillation and auricular flutter, occurred in 8 of 78 patients who received total pneumonectomy but had no evidence of heart disease. In our opinion, these arrhythmias alone do not indicate heart disease.

It seems best to restore the heart to normal rhythm as soon as practicable, either by rapid digitalization or, in selected cases, by quinidine sulfate, since heart failure may result if an excessively rapid cardiac rate continues over many days.

The etiology of these arrhythmias is unknown. The hypothesis is suggested that the precipitating factor is vagal irritation from a stitch abscess or infection of the bronchial stump in the presence of hyperexcitability of the auricular muscle resulting from marked displacement of the mediastinum.

CARDIAC ARRHYTHMIAS FOLLOWING THORACIC SURGERY*

JAMES H. CURRENS, M.D.,† PAUL D. WHITE, M.D.,‡ AND EDWARD D. CHURCHILL, M.D.,§

BOSTON

DISTURBANCES in the rate and rhythm of the heart action are occasionally observed in surgical patients during the postoperative period. The frequency of such occurrences is not high, and no pertinent statistics on this subject are to our knowledge available, although several observers^{1, 2} have noted the frequency of arrhythmias during operation. The uncommonly high incidence of cardiac arrhythmias following thoracic surgery has come to our notice during the last two or three years and deserves some comment. Although at times this complication during the postoperative period is of small consequence and quickly rights itself, at other times it is prolonged and difficult to control. Under such circumstances the physician is confronted with a therapeutic problem that, if not corrected, may result in embarrassment of the heart and the circulation.

In the last few years 12 patients (9 of whom had electrocardiograms) presenting a disturbance in cardiac rhythm following thoracic surgery have been observed in the Massachusetts General Hospital. Nine of these were drawn from a series of 43 patients with carcinoma of the lung who underwent lobectomy or pneumonectomy, a proportion of 21 per cent. The remaining 3 cases were drawn from 13 cases in which exploration (3 cases) or resection (10 cases) of carcinoma of the esophagus was performed. A brief account of these 12 cases is given herewith.

CASE REPORTS

CASE 1. B.M., a 47-year-old Jewish salesman, entered the hospital with a history of productive cough for 7 months, which had been severer for 1 month. For 1 week he had had an intermittent fever as high as 103°F. Physical examination was not remarkable. X-ray examination of the chest revealed an area of increased density that was thought to be due to an abscess of the right lower lobe. On October 14, a right lower lobectomy was performed. Two days later, following the patient's turning on his side and coughing, the pulse became totally irregular at 150 and the lips became somewhat cyanotic. The patient was digitalized in the course of 24 hours, by which time the heart had returned to a normal rhythm. He did poorly, however, and died of infection on October 19, 5 days postoperatively. No autopsy was performed.

Comment. This case illustrates the somewhat transient arrhythmia that may be precipitated by a change of posture. The auricular fibrillation lasted for less than 24 hours.

*Presented before the New England Heart Association, Boston Medical Library, January 18, 1943.

†Research fellow in medicine, Massachusetts General Hospital.

‡Physician, Massachusetts General Hospital; lecturer in medicine, Harvard Medical School.

§Chief of West Surgical Service, Massachusetts General Hospital; professor of surgery, Harvard Medical School.

CASE 2. F.H., a 65-year-old salesman, entered the hospital with the complaints of wheezing, hemoptysis and some shortness of breath for 8 months. Physical examination revealed a few musical rales throughout the chest. The heart was normal. The blood pressure was 130/80. An x-ray film of the chest demonstrated a mass in the left upper lobe that was thought to be a bronchiogenic carcinoma. On October 25, a left pneumonectomy was performed. The blood pressure dropped postoperatively but returned to normal after 1 liter of air under positive pressure was removed from the left chest. Two days later, the pulse was found to be irregular because of frequent auricular premature beats by electrocardiogram, at a rate of 120. The patient was digitalized, since at first the arrhythmia was thought to have been due to auricular fibrillation. Five days postoperatively, auricular flutter was observed with an auricular rate of 360 and a ventric-

FIGURE 1. Case 2.

The electrocardiogram shows auricular flutter with 2:1 auriculoventricular block.

ular rate of 180 with 2:1 block (Fig. 1). The dosage of digitalis was increased, and the following day the ventricular rate was 120 and there were varying degrees of block. Three days later, a normal rhythm at 100 to 120 with auricular premature beats was observed. The following day auricular flutter was again noted, with a ventricular rate of 160 (2:1 block), and the digitalis dosage was again increased. Two days later, the rhythm was regular at a rate of 120. Later the same day the patient became increasingly dyspneic and cyanotic and died of respiratory distress with the pulse remaining at about 120.

Autopsy revealed the following conditions: epidermoid carcinoma of the left lung (previous operation) with metastases to the liver, kidney and right lung; acute postoperative pleuritis, on the left; acute fibrinous pericarditis; bronchopneumonia; and pulmonary edema and emphysema, on the right.

Comment In spite of the intermittent arrhythmia, there were few signs of heart failure until the last few hours of life. The use of digitalis may have accounted, in part at least, for the lack of more evidence of congestive heart failure. In reviewing the case, however, it appears that quinidine might have been used to great advantage to prevent or control the cardiac arrhythmia. The frequent auricular premature beats in the first electrocardiogram were a sign of an irritable heart.

CASE 3 R B, a 41 year-old laborer, entered the hospital complaining of chest pain and wheezing of 6 weeks duration. Physical examination revealed a moderate number of musical rales throughout the chest, with some impairment of breath sounds over the right chest anteriorly. The heart was normal. The blood pressure was 100/60. An x-ray film of the chest revealed a mass at the right lung root that seemed to occlude partially the bronchus to the right upper lobe. On May 2, a right pneumonectomy was performed. The patient did well except for the development of moderate subcutaneous emphysema. On May 13, a tube was inserted in the right thorax for drainage of fluid from an empyema. On May 20, the pulse was found to be totally irregular with an apical rate of 135 and a radial pulse of 90. This, however, was readily converted to a normal rhythm in 3 or 4 minutes when the intrathoracic pressure was changed from negative to positive (-5 cm of water to +2 cm). No recurrence of the arrhythmia was noted, and the patient recovered from the operation.

Comment The cardiac arrhythmia was of small moment, in this case, but it demonstrates a factor that may influence the cardiac rhythm, that is, a change in intrathoracic pressure on one side of the chest. Change in the position of the heart may have resulted from the change of pressure.

CASE 4 K B, a 57 year-old physician entered the hospital for observation because of a mass found incidentally by x-ray in the right lung field. The chest and heart were normal. The blood pressure was 110/70. On April 14, a right upper lobectomy was performed for carcinoma of the lung. The postoperative course was uneventful, although the patient was kept in an oxygen tent. On April 14, after he had been out of the tent for a short while, the pulse reached 160, with some irregularity but without deficit. An electrocardiogram revealed the presence of auricular flutter. The patient was digitalized, and the following day the heart rate had decreased to an average of 90, with varying degrees of heart block, from 2:1 to 5:1. Digitalis was continued and the heart rate was fairly well controlled, in spite of the persistence of the auricular flutter, although at times the rate rose to 120. The patient had a slow convalescence with some cyanosis, mental confusion at times and a high carbon-dioxide blood level, which was apparently due to a poor gaseous exchange in the lungs. In July, quinidine sulfate, 0.4 gm every two hours for six doses, was given in an attempt to restore normal rhythm, but without success. Auricular flutter persisted without acting as a factor of clinical moment until death from cerebral metastatic malignancy occurred the following November.

Comment This case illustrates the long and protracted digitalis was of aid in controlling the ventricular rate.

CASE 5 H L, a 55 year-old merchant, entered the hospital complaining of cough and hemoptysis of 5 months' duration. The heart was normal and the blood pressure was 140/70. X-ray examination of the chest revealed a mass in the right upper lung field, thought to be carcinoma. The electrocardiogram revealed a normal tracing except for an inverted T wave in Lead 4, which was interpreted as being consistent with mild coronary heart disease. Because of a slightly painful right calf with mild swelling of the leg on entry, the right superficial femoral vein was ligated on February 13. On February 24, a right upper lobectomy was performed. Auricular fibril-

FIGURE 2 Case 5

This electrocardiogram, taken four days postoperatively, demonstrates auricular fibrillation with a ventricular rate of about 145.

lation was noted February 28 (Fig 2), at which time some fluid was noted in the right chest and the trachea was deviated to the right. Quinidine sulfate was given, 0.4 gm the first day and 0.8 gm the 2nd day, at which time the rhythm returned to normal. Following this for 4 weeks 0.2 gm of quinidine was given three times a day as a prophylactic measure. On March 5, the patient was suddenly seized with a painful constricting sensation across the chest, with increase in the respiration to 35 and in the pulse to 140, with regular rhythm. On the following day, the electrocardiogram (Fig 3) was quite characteristic of pulmonary embolism with acute cor pulmonale. The same day, tenderness was noted in the left calf, and ligation of the left superficial femoral vein was performed, with removal of a thrombus from the vein. The patient subsequently improved rapidly without further complications.

Comment. It seems likely that quinidine aided in the restoration of normal rhythm. This case also illustrates the occurrence of constricting chest pain quite typical of angina pectoris following a large pulmonary embolism, probably due to decreased coronary blood flow. This is

FIGURE 3. Case 5.

This electrocardiogram was taken nine days post-operatively but less than twenty-four hours following pulmonary embolism.

more likely to occur in a patient who has some antecedent coronary heart disease, as was suggested in this case by the slightly abnormal electrocardiogram. It is also of interest that the patient did not develop auricular fibrillation following pulmonary embolism. The maintenance dose of quinidine may have been of some value in this regard.

CASE 6. E. R., a 56-year-old truck driver, entered the hospital because of morning cough and loss of weight for 6 months. The heart was normal. The blood pressure was 130/70. X-ray examination of the chest revealed a mass in the left upper lung field that was thought to be due to carcinoma. On July 6, a total left pneumonectomy was performed. The course was uneventful until July 9, when auricular fibrillation was noted at a rate of 120. The patient was digitalized, and the heart rate was thereafter controlled. He developed fever on July 20, and died from infection on July 22.

Autopsy revealed the following conditions: epidermoid carcinoma of the left lung, with metastases to the regional lymph nodes and contralateral lung; bronchopleural fistula, on the left; septicemia, nonhemolytic streptococcus; and bronchopneumonia (right lower lobe).

CASE 7. J. G., a 57-year-old salesman, entered the hospital with a diagnosis of probable carcinoma of the left bronchus. Physical examination revealed diminished breath sounds over the left lower lobe. The remainder of the examination was not remarkable. The blood pressure was 120/80, and the pulse was regular. On May 22, left pneumonectomy was performed. On May 24, auricular fibrillation was noted, with an apical rate of 110. The patient was given digitalis, 0.3 gm. daily for 7 days, at the end of which time the apical pulse had decreased to 88. Digitalis, 0.1 gm. daily, was continued until discharge. It is not known whether the rhythm was irregular at discharge, but the rate was 80.

Comment. The auricular fibrillation in this case was of little importance and presented no therapeutic problem during the postoperative course.

CASE 8. W. K., a 56-year-old plumber, was referred to the hospital with a diagnosis of carcinoma of the upper lobe of the right lung. Physical examination was not remarkable, and the blood pressure was 120/80. On May 10, a right total pneumonectomy was performed. Three days later, the heart rate was 160, and an electrocardiogram demonstrated auricular flutter at a rate of 320, with 2 auriculoventricular block. Eight tenths of a gram of digitalis was given in the subsequent 24 hours, at the end of which time a second electrocardiogram revealed a normal rhythm at 120 with frequent auricular premature beats. A brief recurrence of the rapid heart action shown to be auricular flutter with a ventricular rate of 160 was observed both on May 11 and May 12, each lasting about an hour. There were no more episodes of disturbed heart action, and the remainder of the course was uneventful. Digitalis was stopped on May 16.

Comment. Again, the transient nature of the tachycardia is demonstrated. It should be noted, however, that evidence of irritability of the heart was manifested at times, in the absence of auricular flutter, by the frequent auricular premature contractions.

CASE 9. J. McC., a 39-year-old mechanic, was referred to the hospital with a diagnosis of carcinoma of the lung. Physical examination was not remarkable, the heart was normal, and the blood pressure was 110/70. On May 10, a right pneumonectomy was performed. On May 11, auricular fibrillation was noted, with a ventricular rate about 190, and this continued until June 2, when the heart rate was regular at 80 with an occasional extrasystole. Later the same day auricular fibrillation was again noted with a ventricular rate of 195. The patient was digitalized which resulted in a decrease of the ventricular rate to 130. The following day 700 cc. of fluid was removed from the right chest. By June 4, the heart rhythm was again normal at a rate of 80 and remained so throughout the postoperative period. Digitalis was continued until discharge.

Comment. The transient nature of the auricular fibrillation is again notable. The accumulation of fluid in the right chest developed about the same time as the auricular fibrillation.

CASE 10. C. H., a 61-year-old laborer, entered the hospital complaining of difficulty in swallowing of 3 weeks' duration. Physical examination was not remarkable. The blood pressure was 155/90. X-ray examination of the esophagus revealed an irregular filling defect in the n

dle third that was thought to be carcinoma. On July 15 a partial esophagectomy was performed through the left thorax. The postoperative course was uneventful until July 20, when the respirations increased to 30, the pulse rose to 135, and there were physical signs of collapse of the left lower lung. On July 22, the patient became mentally confused and the heart rate was found to be 180. He was digitalized, and the following day the heart rate was regular at 140. The signs of collapse of the left lower lung lobe had disappeared by July 25, at which time the pulse was regular at 95 and the mental confusion had disappeared. Convalescence was uneventful.

Comment. The postoperative period was first complicated by collapse of the left lower lobe, to be followed by the development of auricular flutter and a rapid ventricular rate. Digitalis probably helped to slow the rate and after 3 days normal rhythm was re-established.

CASE 11. C W, a 53-year-old man was admitted to the hospital because of epigastric pain of 5 weeks duration. The heart and lungs were normal. The blood pressure was 140/70. X-ray examination of the esophagus revealed a tumor in the lower third. On August 3, partial esophagectomy was performed through a left thoracic approach. On August 5 auricular fibrillation was noted with a ventricular rate of 180. The patient was digitalized and 3 days later the apical rate was 100 with normal rhythm. The digitalis was discontinued after 7 weeks, and the heart rhythm remained regular. Convalescence was uneventful.

CASE 12. J L, a 49-year-old housewife entered the hospital because of dysphagia of 7 months duration. Physical examination was not remarkable. The blood pressure was 130/80. X-ray examination of the esophagus revealed an ulcerative lesion in the lower third. On September 29 a transthoracic partial esophagectomy was performed. On October 3 auricular fibrillation developed with a ventricular rate of 200. Quinidine sulfate was started and 7.8 gm was given in the first 24 hours. At the end of this time the rhythm returned to normal for 1 hour at a rate of 110, following which auricular fibrillation recurred with a somewhat slower ventricular rate of 140 to 160. The quinidine was continued the patient receiving 2.8 gm during the 2nd day, in 0.4 gm doses. On October 6 the pulse returned to normal and it remained regular thereafter. The following day 1500 cc of fluid was removed from the left chest. Convalescence was uneventful.

DISCUSSION

Of the 12 patients reported here, 8 developed auricular fibrillation and 4 developed auricular flutter. In 2 cases auricular premature beats were noted either preceding or subsequent to the tachycardia. In no case was there noted a change from auricular flutter to auricular fibrillation or vice versa, but in 4 cases there was at least one recurrence of the arrhythmia following a restoration of normal rhythm. Thus quinidine therapy seems to be justified if auricular premature beats develop or even following the restoration of normal rhythm to prevent any further arrhythmia. It can also be used as a prophylactic measure, particularly in patients who undergo partial esophagec-

tomy, since 3 of 10 patients in our experience developed cardiac arrhythmia. Quinidine sulfate, 0.2 gm three or four times a day, has proved effective in this regard. This need not be given until after the operation, since the arrhythmia does not develop until from two to eighteen days postoperatively.

It is undoubtedly significant that all the patients reported here were thirty-nine years of age or over, the average being fifty-three and range from thirty-nine to sixty-five. In a considerably larger series of patients who underwent lobectomy or, less frequently, pneumonectomy for bronchiectasis of the lung, no cases of arrhythmia of the heart were observed. The ages in that series were much lower, ranging from about fifteen to forty years. Age, then, is a predisposing factor in the development of cardiac arrhythmias following thoracic surgery. This has been noted likewise in patients with otherwise normal hearts in whom a cardiac arrhythmia develops.¹⁻³

In the series of 12 cases reported here, examination of the heart gave no evidence of valvular disease. In 1 patient (Case 5) there was some electrocardiographic evidence of coronary heart disease. However, it has been noted by several observers^{1,2} that there seems to be no significant association of auricular fibrillation and coronary heart disease. It seems likely, therefore, that coronary heart disease played no important role in the development of the cardiac arrhythmias in this series. It is true that all the patients had carcinoma, but this is undoubtedly irrelevant.

The cause of the development of the arrhythmias remains obscure although there seemed to be precipitating factors in several cases. In 3 cases the development of empyema coincided with the onset of the arrhythmia of the heart, and in 1 there was significant collapse of the lung that developed concomitantly. The change of posture of 1 patient seemed to have initiated the cardiac arrhythmia. Pericarditis was found at necropsy in 1 case, but it seems unlikely that pericarditis was an important etiologic factor in this series.

In treating the patient who develops an arrhythmia the physician has the choice of giving no special treatment, since most of these patients spontaneously reestablish normal rhythm in the course of two or three days of attempting to control the ventricular rate by the use of digitalis and waiting for the normal rhythm to return or of attempting to hasten the restoration of normal rhythm by quinidine sulfate. The decision should be based on the condition of the patient, since immediate therapy may be necessary to avert congestive heart failure. Rapid digitalization is then indicated. If there is no imminent danger of

congestive heart failure, a course of quinidine sulfate, 0.4 gm. every two to three hours for six doses, or until normal rhythm is restored, is the treatment of choice. If this fails, the same course may be repeated, using 0.6 gm. every two to three hours under careful electrocardiographic control.

SUMMARY AND CONCLUSIONS

Cardiac arrhythmia is occasionally noted following thoracic surgery. Twelve patients are reported from a series of 56 who underwent surgery for carcinoma of the lung or esophagus. Eight had auricular fibrillation, and 4 auricular flutter.

Age appears to be a predisposing factor, since arrhythmia of the heart seldom occurs following thoracic surgery below the age of forty.

Quinidine sulfate may be used to advantage in such patients as a prophylactic measure during the postoperative period.

Since the above report was compiled, a thirty-year-old woman has been observed who developed nodal tachycardia at a rate of 180 fifteen hours after a left lower lo-

bectomy for tuberculosis and bronchiectasis. A course of quinidine sulfate, 0.4 gm. every two hours for five doses, was given during the first day without effect on the tachycardia. The patient was also digitalized during this time by the administration of 1.6 mg. of lanatoside C intravenously. A second course of quinidine was given, consisting of 0.6 gm. every two hours, and after the fourth dose, thirty-six hours after the onset of the tachycardia, the rhythm returned to normal and the pulse dropped to 110. Quinidine sulfate, 0.4 gm., was continued every six hours in an effort to prevent the recurrence of the paroxysmal tachycardia. The patient developed increasing cyanosis and died of infection on the fourth postoperative day. The pulse rate remained between 110 and 120 until the time of death.

MEDICAL PROGRESS

BRIGHT'S DISEASES*

STANLEY E. BRADLEY, M.D.†

BOSTON

DESPITE considerable elaboration since the original description by Bright more than one hundred years ago, the group of nephropathies now embraced by the term "Bright's diseases" continues to pose many problems in etiology, pathologic physiology and therapy. In discussing this group of renal disorders, usually defined as the bilateral nonsuppurative nephropathies, a logical classification is desirable. The threefold classification of Volhard and Fahr¹ continues to be popular, either in its original form or in various modifications. Volhard and Fahr's division of Bright's diseases into the inflammatory nonsuppurative nephropathies (nephritides), the degenerative nephropathies (nephroses) and the vascular nephropathies (nephroscleroses) has had a new modification during the past year by Ellis²⁻⁴ in England. He also proposes three groups of entities—nephritis, essential hypertension and a miscellaneous

group. The present review will follow, in the main, the classification of Volhard and Fahr, but will be confined to a discussion of the nephritides and the nephroses. The omission of the nephroscleroses is dictated by the desire to avoid repetition, for this subject is usually discussed with essential hypertension and should be considered in relation to all aspects of hypertension.

THE NEPHRITIDES

Glomerulonephritis

The pathogenesis of glomerulonephritis remains obscure. A considerable amount of work has incriminated the streptococcus as the commonest etiologic agent, although other infectious agents have been implicated as causative factors in isolated cases. There seems to be little doubt that upper respiratory infections, usually by beta-hemolytic streptococci, precede the attack of acute diffuse glomerulonephritis in the vast majority (90 per cent in one series⁵) of cases in this country. It is interesting to note the comment made by Snapper⁶ that a superficial pyodermitis is the usual form of infection preceding acute diffuse

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942, \$5.00).

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor in medicine, Boston University School of Medicine.

glomerulonephritis in China. However, Seegal and Earle⁷ found that approximately two thirds of their patients with glomerulonephritis had a "deep" infection. Additional evidence incriminating the streptococcus in most cases of nephritis is to be found in changes in the antistreptolysin titer during the disease, with an increased titer appearing in the acute stage.⁸ During the past year it has also been found that the titer increases in the course of exacerbations of chronic diffuse glomerulonephritis and that the magnitude of the increase is correlated with the severity of the exacerbation and not with the severity of the preceding infection.⁹⁻¹⁰ The increase in antistreptolysin titer is often valuable in detecting a recent infection by Group A hemolytic streptococci, although the organisms may not be demonstrable by culture.

Just how the streptococcus damages the kidney is unknown, for there is no evidence that it directly invades the kidney or has a nephrotoxic effect. Attempts to produce nephritis in animals with streptococci and their products have been on the whole, inconsistent and unsatisfactory. However, a type of glomerulonephritis closely resembling the human form has been produced in animals by the use of "nephrotoxic" serums and may throw light on the mechanism of damage by the streptococcus. So-called "nephrotoxic nephritis" may be produced in the guinea pig, dog, cat or rabbit by injecting serum from ducks or chickens previously subjected to sensitizing doses of kidney tissue from the same species in which the nephritis is to be induced.¹¹ On the surface, this nephritis appears to be caused by a simple reaction between antigen (the recipient animal's kidney) and antibody (the donor's serum). However, if this were the case, the reaction would be expected to occur immediately instead of after five to eight days, as actually found. Moreover, the development of nephritis seems to depend on the presence in the recipient's blood of antibodies reacting with the donor's serum. These antibodies are manufactured during the latent period, and their appearance in the blood marks the onset of nephritis. Kay¹¹ has shown that suppressing the production of these antibodies by roentgen radiation prevents the nephritis, whereas after radiation the injection of antibodies from another animal results in an immediate onset of nephritis. Thus it appears that the first antigen antibody reaction is harmless, but when antibodies to foreign serum are present, a complex is formed that is nephrotoxic. The sequence of events in this type of nephrotoxic nephritis is similar to that in human nephritis, in which a latent period of three to twenty-eight days

elapses following the initial infection before the acute episode is manifest, and is consistent with the concept of the causation of human nephritis advanced by Schwentker and Comploier¹² in 1939. In their view streptococcal products unite with the human kidney tissue to form a compound harmless in itself but causing antibody formation. The combination of the new antibodies and the original antibody antigen complex is nephrotoxic.

Studies of the course of glomerulonephritis require many years of careful, tedious and arduous work to come to fruition because of the duration of the disease and the vagaries of its course. During the past year several reports have appeared dealing with the finding of various groups of workers in this field. Ellis²⁻⁴ devoted his Croonian Lectures to a discussion of the natural history of Bright's disease, the result of twenty years' work. He states that glomerulonephritis appears in two forms, which he designates simply as "nephritis I" and "nephritis II." Nephritis I is the commoner of the two forms and appears predominantly in the first two decades of life. It is characterized by a sudden onset of the classic acute diffuse glomerulonephritis, usually following an upper respiratory infection. It proceeds in 82 per cent of cases to complete recovery, but in 10 per cent the disorder becomes latent with persistent proteinuria, terminating as a rule many years later in hypertension and renal insufficiency. Ellis is apparently of the opinion that the nephrotic syndrome is never seen in this group of patients, although it becomes the outstanding clinical manifestation in nephritis II. In this type of nephritis, a much smaller group, the onset is insidious, frequently without a history of a preceding infection, and occurs predominantly in persons in the second and third decades of life. Massive edema, hypoalbuminemia and albuminuria are the dominant and diagnostic features, and nearly all cases progress to a fatal termination in hypertension and uremia. Autopsy material is presented to support the claim that nephritis I and nephritis II are not only clinically unlike but are also definite pathologic entities.

Murphy and Peters¹³ have reported a follow up study of 205 cases of acute diffuse glomerulonephritis. Their findings are in agreement with those of the English workers in indicating a more serious prognosis in those patients who display edema after the first week or two of the disease. They emphasize that they find in their cases of acute nephritis a chronicity rate of at least 59 per cent, a figure in striking contrast to the much more favorable reports elsewhere in the literature. In neither their nor Ellis's study were the length and type of course subjected to further analysis, al-

though they agree on the variability and usual length. In this regard Horn, Klemperer and Steinberg¹⁴ have made an interesting contribution, offering evidence to support the notion that the course of chronic diffuse glomerulonephritis may be divided into two phases, one slowly progressive and the other accelerated. This view is based on a clinicopathological study of 49 cases in which the anatomic equivalents of the changes seen in the benign and malignant phases of essential hypertension were found at autopsy. These changes were associated with histories of slow and of rapid progression, respectively. The authors believe that their data support the hypothesis that prolonged hypertension is the factor exciting acceleration.

There is a varying opinion regarding the prognosis of the initial acute phase of glomerulonephritis. In 495 cases brought together from seven reports, Hayman and Martin¹⁵ found a range of 42.5 to 85.4 per cent cured, 17.3 to 32.0 per cent latent and 3.8 to 41.7 per cent going into chronicity. The greatest difficulty in prognosis is encountered during the latent phase into which many patients pass following the acute attack. This phase may be characterized by the complete absence of outright evidence of renal damage and is often mistakenly overlooked, or the patient is labeled as cured. Addis¹⁶ was one of the first to emphasize the importance of this stage and to study it carefully with a technic of exacting urine examinations, including quantitation of the formed elements in the urine. Addis's method of counting the cells and casts in the urinary sediment continues to be a helpful adjunct in evaluating the progression and prognosis of the disease. Its superiority to the routine urinalysis is seen in the figures of Rubin, Rapoport and Waltz.¹⁷ They found that the routine urinalysis returned to normal on the thirty-seventh day on the average, whereas a normal Addis count required an average of one hundred and twenty days. In addition, they found the sedimentation rate to be as reliable a prognostic index as the Addis count. Murphy and Peters¹³ also recommended the sedimentation rate as a measure of the activity of the disease. From a practical standpoint, the technical simplicity of the sedimentation rate seems to recommend it as a valuable aid in following patients in the latent stage of glomerulonephritis.

There seems to be general agreement that rest is of first importance in the treatment of both the acute episode and the chronic form of glomerulonephritis. Murphy and Peters¹³ state that the patient should be kept in bed until all clinical features and every evidence of nephritis have disappeared, or up to a period of four months. Of

their patients, 27 per cent of those discharged with minimal activity became latent, whereas only 14.9 per cent of those discharged with negative urines went on to latency. However, many workers believe that there is no necessity limiting activity so long as hypertension and edema are absent. It is also agreed that dietary restrictions are indicated in the presence of azotemia and edema. In the former, protein should be limited, and in the latter, the restriction of salt and water is necessary. Whether protein should be cut down in the absence of azotemia remains a moot point. There is no clinical evidence that protein has any detrimental effect¹⁸ and much evidence that protein lack can be harmful. On the other hand, protein feeding has been shown to increase the renal damage of experimental nephritis in animals.^{19, 20} Most clinicians attempt to steer a middle course—the restriction of protein to minimal requirement levels.

The proof that localized infection and particularly infections of the upper respiratory passages and paranasal sinuses may give rise to glomerulonephritis has resulted in an earnest search for and eradication of focal infection. There is no evidence that these procedures ameliorate, interrupt or prevent the renal process. Illingsworth,²¹ studying 119 children with chronic diffuse glomerulonephritis, could find no evidence that the course of the disease was altered by tonsillectomy. Nor could he demonstrate that tonsillectomy was of value in prophylaxis, since 20 per cent of a large series of patients had had tonsillectomy at some time before the onset of the acute nephritis. In another series, seen at the Babies' Hospital in New York City, approximately one third had had their tonsils out before onset.²² Although it seems wise to remove tonsils and eliminate foci of infection in certain cases, this should not be done with the hope of affecting the nephritic process.

The effectiveness of chemotherapy in acute infections, particularly in those of streptococcal origin, has aroused the hope that the sulfonamides might prove effective in prophylaxis, in controlling and terminating the acute attack and in preventing exacerbations. This hope has been given some substance during the past year by the work of Williams, Longcope and Janeway.²³ These investigators treated a series of 42 cases of acute nephritis with sulfanilamide, using an untreated group of 108 comparable cases as controls. They concluded that foci of infection cleared up more rapidly, signs of renal damage disappeared more quickly, exacerbations occurred less frequently, the duration of the edema and the hypertension was shorter, and clinical recoveries were more frequent under sulfonamide therapy than in the

control group. Although their conclusions seem warranted by the data obtained, they were not able to present persuasive evidence on every point mainly because of the irregularity of the course of the disease and the relatively small number of cases in their series.

Embolie and Other Forms of Glomerulonephritis

Whether the renal lesion appearing in the course of subacute bacterial endocarditis should be included among the nephritides is disputable, although it is widely classified as acute focal embolic glomerulonephritis.²⁴ Christian's^{25, 26} work during the past year seems to support the idea that the lesion is inflammatory, at least in part. He was impressed by the nonspecificity of the glomerular lesions, which resembled those attributable to other glomerular damaging agents, such as acute diffuse glomerulonephritis, pyelonephritis and toxemia of pregnancy. In a series of 61 autopsies he found slight swelling and edema in almost all kidneys, hemorrhages varying from scattered petechiae to the typical "florid" kidney in 13 per cent and areas of infarction in 92 per cent. In 80 per cent the lesions were typical of those seen in intracapillary glomerulonephritis with diffuse proliferative intracapillary lesions, whereas in 16 per cent hyaline thickening of the capillary walls was observed. In addition, epithelial crescents were found in 36 per cent, with evidence of damage to the tubular tissue ranging from focal fibrous lesions in 26 per cent to complete disorganization in a few.

Other conditions in which acute diffuse glomerulonephritis is frequently seen are the visceral angitides, including periarteritis nodosa, lupus erythematosus and Libman-Sacks disease. A study by Krupp²⁷ of the urinary findings in 21 cases of these disorders revealed an apparently specific picture in 14 consisting of the concurrence of red cells, red cell casts, oval fat bodies, fatty casts, broad casts and heavy proteinuria. He believes this concurrence to be of diagnostic significance. The concept of Klemperer, Pollack and Baehr²⁸ that lupus erythematosus is a widespread disease of the collagenous connective tissue will undoubtedly inspire extensive investigation. This hypothesis is based entirely on pathological grounds and has as yet found no experimental proof. However, Rich's²⁹⁻³¹ belief that periarteritis nodosa is a manifestation of hyperergy resulting from sensitization to foreign protein or drugs, such as the sulfonamides, appears to rest on firm experimental evidence. The discovery of extensive fresh lesions of periarteritis nodosa in 7 consecutive autopsies of persons dying in the midst of serum sickness or at the height of a sulfonamide reaction as well as the

experimental production of the lesions in rabbits during delayed reaction to foreign serums, gives strong support to his view. The finding of vascular lesions in rabbits following the production of antibodies to foreign serum has an important bearing on nephrotoxic nephritis, for the production of which these antibodies have been found necessary. Further exploration of the possibilities thus disclosed will undoubtedly add to the knowledge of the causation of many of the nephritides.

Pyelonephritis

Pyelonephritis has taken its place as a member of the group of Bright's diseases only during recent years, mainly as a result of the work of Longcope³² and of Weiss and Parker.³³ The recognition that pyelonephritis can cause hypertension, with the terminal picture, clinically and pathologically, of chronic diffuse glomerulonephritis and malignant nephrosclerosis, and the realization that its initial lesion is amenable to modern therapy, has resulted in a voluminous literature. The acceptance of pyelonephritis with contracted kidney as a form of Bright's disease has not yet found its way into the textbooks, but in the current literature it is tacitly or explicitly regarded as such.³⁴ The fact that many cases of the affection are unrecognized in their incipency raises the question of the relation of pyelonephritis to essential hypertension. The weight of the evidence, however, seems to support the belief that the disease is only slightly more frequent among hypertensive than among normotensive persons. Thus, Shure³⁵ in a review of 11,898 autopsies at the Cook County Hospital in Chicago discovered only 290 cases of pyelonephritis, with hypertension in 44.4 per cent as compared with 34.9 per cent in a control group. Among children, only 10 per cent of 79 cases were hypertensive.³⁶ Moreover, pyelonephritis seems to be a relatively rare disease (in Shure's series 2.44 per cent of the autopsies) and since less than half of these were hypertensive it does not seem likely that pyelonephritis is often an occult cause of essential hypertension. Harrison and Bailey³⁷ emphasize the importance and frequency of this condition as a complication of diabetes, since asymptomatic lesions leading to necrotizing pyelonephritis and death may occur in some 20 per cent of diabetic patients. Bowen and Kutzman³⁸ found an even higher percentage of involvement of the urinary tract in diabetic patients (51 of 84 cases), and they re-emphasized the difficulty of diagnosis. Actually the rarity of the lesion may be more apparent than real since it may be unrecognized pathologically because of the terminal resemblance to chronic diffuse glomerulonephritis and nephrosclerosis. A higher incidence might

be found if the pathological criteria of Weiss and Parker³³—an inflammatory reaction in the interstitium, colloid casts in the tubules, periglomerular fibrosis and evidence of infection or inflammation within the tubules—were kept in mind and applied.

An excellent review of the problems and literature of the glomerulonephritides by Matthews³⁹ has appeared during the past year.

THE NEPHROSES

The group of disorders embraced by the nephroses are diverse in etiology and clinical manifestations, unified only by the fact that in all of them the tubular tissue contains lesions ranging from cloudy swelling with deposits of lipoid and hyaline material to profound necrosis. On the whole, they can be divided into two major categories: those in which the tubular lesions are as a rule of minor importance, with the nephrotic syndrome or proteinuria alone dominating the clinical picture, and those in which necrotic lesions of the tubules are outstanding, associated with few, if any, of the features of the nephrotic syndrome.

Among the entities included in the first group are lipoid nephrosis, amyloid disease of the kidney, intercapillary glomerulosclerosis, nephrosis due to deposit of Bence-Jones proteins in the tubules during myelomatosis—and as minor variants the so-called “larval nephroses”—and benign and orthostatic albuminuria. In all these the common denominator is proteinuria of varying degree. The pathogenesis of the proteinuria remains unknown and controversial, but it is widely held that glomerular capillary permeability is the determinant of the quantity of protein appearing in the urine. Dock⁴⁰ has advanced the thesis, on the basis of studies of the behavior of large protein-bound dye molecules, that a considerable amount of protein traverses the glomerular membrane normally and is reabsorbed by the tubules. In his view such entities as benign albuminuria, orthostatic albuminuria and other varieties of moderate protein loss may be attributable to tubular dysfunction rather than to increased permeability of the glomerular capillaries. Nonetheless, in cases of major proteinuria his concept must also embrace the notion of increased glomerular capillary permeability. Dock's hypothesis seems to gain support from the work of Smetana and Johnson.⁴¹ These workers found that the colloidal and lipoidal droplets in the tubule cells of urodeles are derived from reabsorbed protein, a finding that indicates the possibility of protein reabsorption in the mammalian kidney and offers an explanation for some of the pathological findings in the nephrotic syndrome. An extensive study by Blackman, Goodwin and Buell⁴² throws

light on the components of lost protein and the significance of various types of proteinuria. In general it appears that albumin makes up the largest moiety of the protein lost, but in conditions of progressive renal failure associated with the appearance of fibrin and organized exudates within the kidney there is high globulinuria. Fatal cases of acute diffuse glomerulonephritis associated with high proteinuria and globulinuria showed extensive deposits of fibrin within Bowman's capsule, unlike fatal cases in which the proteinuria was of low concentration. However, the loss of protein in the urine, no matter what its mechanism, is the cause of the clinical picture in those conditions where proteinuria becomes excessive, for protein loss in excess of restoration causes hypoproteinemia, a lowered plasma oncotic pressure with subsequent edema, and the full-blown nephrotic syndrome.

The nephrotic syndrome is not limited to the nephroses, for it frequently appears in acute diffuse glomerulonephritis or in the course of chronic diffuse glomerulonephritis. It is interesting that this picture is always associated with an increase in the plasma lipids. The increase in blood lipid is regarded by some as a mechanism by which the lowered oncotic pressure may be compensated. However, Farr, Smadel and Holden⁴³ have shown that hyperlipemia is a constant feature of severe nephritis induced in rats by antikidney serum when there is no hypoproteinemia, and Heymann⁴⁴ reports that lipemia may occur on the basis of tubular damage in the absence of a decreased oncotic pressure. Heymann found a continuous rise in cholesterol and an even greater elevation in total fat following bilateral nephrectomy and fatal renal damage by mercury or uranium, but the levels returned to normal following hypertrophy of the remaining kidney after unilateral nephrectomy or healing of the renal damage. Winkler and his co-workers⁴⁵ also found an elevation in the phospholipids after bilateral nephrectomy and ligation of the ureters, but were unable to obtain increases after unilateral nephrectomy. They showed that the response was nonspecific, occurring in the monkey as well as in the dog, and was not due to fasting, dehydration or reduced plasma volume. An increase in the liver lipids indicated an extrahepatic source, and they expressed the opinion that the hyperlipemia might be due to a disturbance of a renal role in fat metabolism. In addition, Moschowitz⁴⁶ found that hyperlipemia appeared in many conditions in which there was decreased metabolism, and he postulated that the hyperlipemia was caused by the decreased metabolism consequent on generalized edema. Thus there is no evidence that a disturbance of lipid metabolism is of primary im-

portance in lipid nephrosis except as a phenomenon secondary to other changes.

Whether lipid nephrosis is a distinct disease entity dominated clinically by the nephrotic syndrome, pathologically by lipid deposits in the tubular cells and anamnestically by the absence of preceding renal disease, often with a fatal termination in the "nephrotic crisis" (explained below), is not certain. It is quite clear that the picture of lipid nephrosis is extremely rare, for Schwarz, Kohn and Weiner⁴⁷ have seen but 40 cases in a twenty-year period at the Mount Sinai Hospital in New York City, where proportionately more cases are observed than elsewhere because of the intense and long-standing interest in the subject among many workers there. Of these 40 patients, 22 are now dead, of whom 12 were examined post mortem. At autopsy 5 showed definite glomerular changes. One case proved particularly interesting, for an onset of typical acute diffuse glomerulonephritis was followed by a typical clinical picture of lipid nephrosis and death due to pneumococcal peritonitis. At autopsy only an occasional glomerulus with a thickened capsule and swelling of the tuft adjacent to it was found. The authors conclude that most children with the classic clinical picture have glomerular involvement, but perhaps in a different form than that seen in chronic or latent glomerulonephritis. Moschowitz,⁴⁸ a member of the same group, concludes

The validity of "lipid nephrosis" as a distinct disease entity depends on whether it possesses a precise background clinically and morphologically. Clinically "lipid nephrosis" can be differentiated from conditions that simulate it only by arbitrary criteria. Anatomically, "lipid nephrosis" has no specific or consistent background. . . . In the last analysis, "nephrosis" is not a disease and requires precise definition when the term is employed.

In any event, as Farr⁴⁹ has pointed out, the physiologic features and therapeutic implications remain unchanged regardless of the final position of the syndrome nosologically.

Considerable advances have been made during the past few years in knowledge of the physiopathologic phenomena associated with this syndrome. Farr⁴⁹ has recently written an admirable review of these advances, for many of which he and his colleagues are responsible. He is attracted to the idea that the syndrome is not essentially a renal affair. This notion finds support in the finding of a normal kidney function as measured by the urea and inulin clearances and in the evidence of a disturbance of protein metabolism. In both children and adults with the syndrome there is difficulty in maintaining nitrogen equilibrium even on high-protein diets. In addition, there appear to

be abnormalities of the plasma proteins demonstrable immunologically and electrophoretically. Additional evidence that a defect in protein metabolism is responsible for nephrosis is found in the frequent occurrence of what Farr calls the "nephrotic crisis" associated with hypoaminoacidemia. The nephrotic crisis consists of an acute febrile episode with symptoms of peritonitis in the presence or absence of peritoneal infection. Farr and his associates have shown that these episodes are usually preceded by an accelerated loss of urinary nitrogen and a drop in the plasma level of the aminoacids. Intensive treatment with intravenously administered aminoacids or casein hydrolysates has not prevented or halted these episodes but seems definitely to have lessened the fatalities from them. In 32 cases treated with aminoacids, Emerson and Van Slyke⁵⁰ had no deaths, as contrasted with 66 per cent mortality when aminoacids were not used.

(To be concluded)

CASE 29341

PRESENTATION OF CASE

A thirty-six-year-old white bank clerk entered the hospital because of increasing dyspnea of three months' duration.

The patient had had a long history of respiratory distress. Nineteen years prior to admission, while in college, he had had two attacks of pneumonia within a few months. Tuberculosis was suspected but chest plates failed to confirm the diagnosis. For the next ten or twelve years he was well except for more than the usual number of colds. Seven years before entry he was examined for life insurance; in view of his past history an x-ray film of the chest was taken which showed a lung tumor. He was admitted to an outside hospital where, following artificial pneumothorax, an exploratory thoracotomy was performed. A diagnosis of inoperable malignant tumor of the lung was made. He recovered from the operation and returned to work, free of symptoms.

During the next two years he lost about three months each year from his work because of upper respiratory infections. He was given x-ray treatment every three months. Two years later, that is, three years prior to admission, he had pneumonia again. About one year prior to admission he was told by his physician that they had considered his lung tumor malignant and incurable but that since he had lived for so many years they had become convinced that the tumor was benign. For the following two or three months he developed episodes of palpitation, which he believed were due to "nerves." These passed off and did not return. Three months prior to admission he had the gripe. Following this there was a gradual onset of dyspnea, which prevented him from walking up hill or climbing stairs. Three weeks before entry the dyspnea cleared up for a short time, but soon returned and became progressively worse. There was no history of tuberculosis.

Physical examination showed a thin, pale man with a sallow complexion. There was some in-

creased prominence of the veins of the forehead and neck. The left border of cardiac dullness was 16 cm. to the left of the midline in the seventh interspace. The heart was otherwise normal. The lungs showed dullness over the right apex, becoming flat at about the level of the fourth rib. The entire right lower lung was flat, with absent breath sounds and decreased fremitus. The left lung was resonant, but there were occasional rales at the base. The abdomen was negative except for a tender liver edge, which could be percussed 8 cm. below the costal margin.

The blood pressure was 110 systolic, 90 diastolic. The pulse rate was between 100 and 130, and the respiration between 20 and 25. The temperature was normal.

The hemoglobin was 11.3 gm. per 100 cc., and the white-cell count 13,600. A blood Hinton test was negative. Two sputum examinations were negative for tubercle bacilli.

An x-ray film of the chest showed complete obscuring of the lower two thirds of the right lung field by fluid. The right upper lung showed increased density with honeycombing. A grid film showed the right main bronchus visible for about 2 cm., beyond which it could not be made out. The left lung field was clear. The heart shadow was tremendous, and the configuration suggested pericardial effusion (Fig. 1). Fluoroscopically no pulsation was demonstrable. The mediastinum was not displaced. Repeated x-ray examinations revealed no additional findings. A chest tap in the eighth space in the subscapular region yielded 30 cc. of light-amber fluid, followed by 220 cc. of what appeared to be whole blood. This was removed from several directions and depths. A repeat tap in the seventh space in the midaxilla again yielded 30 cc. of blood. No tumor cells were seen in the fluid, which contained innumerable red cells. Two days later the venous pressure was recorded at 330 mm. of water (normal control, 137 mm.). The patient was refluoroscoped at that time. A definite pulsation of the heart could be seen. No change in the contour of the heart could be demonstrated on changing the position of the patient from erect to horizontal. The left border of the heart shadow was convex and without any break in the smooth curve to indicate the limits of the pulmonary conus and left ventricle. Laminography showed the right main bronchus to end sharply 2 cm. from its bifurcation (Fig. 2). No air could be seen entering the lower and middle lobes. There was narrowing of the upper bronchus extending into the aerated portion of the lung. Several small air-filled areas were seen in the region of the lower lobe. A dense soft-tissue mass was seen lying between these and the

*On leave of absence.

blocked right main bronchus. The outline of the mass could not be clearly defined. An electrocardiogram was interpreted as showing sinus tachycardia, with a rate of 120, slight right-axis deviation, low T_1 , total inversion of CF_2 and a very low T in CF_4 and CF_5 .

The patient's dyspnea increased progressively. He died on the twelfth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. C. SIDNEY BURWELL*: I should like to try to reconstruct some stages of this gentleman's

tion from either the superior or inferior caval areas. We do not have a measurement of the venous pressure on the femoral vein, but there was evidence on physical examination that the liver was greatly enlarged and tender. I should accept that as evidence that he had an elevated pressure in his whole venous system. To that should be added the observation on his pulse pressure, which was very low, — only 20 mm., — with a low systolic and a high diastolic pressure. No statement is made about the presence or absence of paradoxical quality. The patient had an extremely rapid

FIGURE 1. *Roentgenogram of the Chest.*

course, beginning at the time he came into the hospital, to see what specific statements we can make that seem reasonably acceptable concerning the anatomic and functional situation of the heart and lungs.

In the first place it seems to me demonstrable that this man had an interference with the entry of blood into his heart—that he had pericardial tamponade. This conclusion is based on the following observations. He had distended neck veins and an elevated venous pressure; there is no mention of the development of collateral circula-

tion from either the superior or inferior caval areas. We do not have a measurement of the venous pressure on the femoral vein, but there was evidence on physical examination that the liver was greatly enlarged and tender. I should accept that as evidence that he had an elevated pressure in his whole venous system. To that should be added the observation on his pulse pressure, which was very low, — only 20 mm., — with a low systolic and a high diastolic pressure. No statement is made about the presence or absence of paradoxical quality. The patient had an extremely rapid

heart rate without fever, again a characteristic finding in those who suffer from obstruction of the entry of blood into the right side of the heart. This conviction of the presence of cardiac tamponade is strengthened by the observations that seem to indicate that he had a pericardial effusion of considerable size—namely, a very large heart shadow and what could be described as an "expressionless" heart, which neither moved nor exhibited the landmarks on the contour which we are accustomed to recognize. Thus he had a large, nonpulsating, smooth, heart shadow, combined with evidence of obstruction to the entry of blood into the heart, and I think we can say

*Research professor of clinical medicine and dean, Harvard Medical School

that he had pericardial effusion, with obstruction to the flow of blood from the venous system into the heart.

Now let us turn our attention to the pulmonary situation at the time he came into the hospital. That also seems to me to be impressive from the point of view of its mechanics rather than from the point of view of information concerning its etiology. The patient had, quite clearly, a long history of progressive obstruction to the bronchi

series of collapses of the middle and right lower lobes, ending up in the situation in which he entered the hospital. More recently he had probably had beginning obstruction of the upper branch of the right main bronchus, with a similar change in the right upper lobe. Thus I should place pericardial effusion and pericardial tamponade as the first part of our diagnosis, and bronchial obstruction with atelectasis and bronchiectasis as the second.

FIGURE 2. Laminogram Showing Obstruction of the Right Main Bronchus just below the Upper-Lobe Orifice.

of the right lung. I surmise that the course of events was an obstruction to one or the other branch of the right bronchus, leading to atelectasis beyond the point of obstruction and to the development of bronchiectatic cavitation, probably recurrent infections in the atelectatic lung, destruction of lung tissue and the leaving of this honeycombed structure as the late result of bronchial obstruction. It seems to me that that meets the situation better than the possibility—the remote possibility it seems to me—of congenital polycystic disease of the lung. This man, I should say, had had a

Then we come to the most important and difficult part of the discussion—the basis for these mechanical changes in the lung and heart. Are they to be placed fundamentally on an inflammatory disease or on a neoplastic basis? Let us consider the possibility of a unitarian basis—that everything can be explained on one etiologic factor. What about tuberculosis? We know that tuberculosis of the bronchi is commoner than we thought; that enlarged lymph nodes in the mediastinum or the hilus of the lung may invade the bronchi and lead to inflammatory stricture and to

obstruction. Let us consider the possibility that he had reactivation of the mediastinal nodes and invasion of the pericardium by tuberculosis. It seems to me there are at least three very important pieces of evidence against the hypothesis that it had been or was tuberculosis, particularly the latter. One is the fact that he was quite free of fever, and I take it that the observation of a normal temperature was not a single isolated reading at a moment after a cold bath or something of that sort, but did really reflect the situation while he was in the hospital. I see from the chart that he never had fever over 101° F. and that it was usually around 99° . That seems to me strong evidence, not final, against an active pericardial tuberculosis. The second piece of evidence against the possibility of tuberculous pericarditis is the presence of blood in the fluid that was removed presumably from the pleural cavity. It may have been removed from some other cavity in relation to the right lung, since the first tap conceivably might have been into the pericardium; but wherever it came from the fluid was so bloody that it was less characteristic of a tuberculous lesion than of a neoplasm involving either the pleura or the pericardium, or both. There is no particular case for the position, so far as I can find out, that a primarily tuberculous lesion may undergo malignant degeneration and be the site of tumor. Another important argument against the presence of tuberculosis is the observation seven years before entry, when his chest was opened and the surgeon, who had the inestimable advantage of a direct view, saw something he believed to be an inoperable malignant tumor of the lung. It is conceivable that that was on a tuberculous basis, but I think that it is much likelier to have been a neoplasm.

If we set aside tuberculosis, we are then confronted with the necessity of postulating a neoplasm. This is certainly the commonest cause of bronchial obstruction. Assuming it was a tumor, it had the extraordinary dual capacity of existing at least seven years—possibly more—and at the same time having done something recently that sounds very much like malignant invasion of neighboring structures. We must consider various types of benign tumors that obstruct the bronchus,—the adenomas and various other ones,—some of which may undergo malignant degeneration after years of growing. We must consider lymphoma. It does not appear in the record whether or not the x-ray treatment, which was faithfully administered, had any effect. However, if it had had an effect, we probably should have been so informed. I am trying to interpret that evidence, such as it is, as indicating that it was not the type of specific improvement after

x-ray that we should expect if we were dealing with a lymphoma.

There is a curious silence about the state of this man's cough and sputum. I think one must interpret that as indicating that cough and sputum were not remarkable, and I derive from that the suggestion that hemoptysis was not a vigorously presenting symptom.

So we have quite an assignment—a neoplasm that obstructed the bronchus but did not produce much cough, did not produce large amounts of sputum, did not lead to hemoptysis and had lasted all these years, to explode in an extension to the pleural and pericardial cavities. At the time of the onset of his disease, this man was twenty-nine years old, a situation that further narrows the probabilities regarding the nature of the hypothetical neoplastic process. I do not think, by the way that he had an aneurysm. There is no suggestion in his history or in the serologic findings. The patient was too youthful to have had an aneurysm that lasted as long as this, and I do not believe that the blood that came out at the time the chest tap was done was due to the entrance of the needle into an aneurysm.

If we ask ourselves what are the types of neoplasm that might fulfill this order, we certainly should have to consider carefully the small group of tumors arising from the mediastinum—the dermoid cyst, the teratoid tumor and so on. These do occur in men of this age. Most of them make themselves known before thirty or forty. Most of them have announced themselves, if they are going to grow, by the time the patient is forty. They almost always start in the anterior mediastinum and are more apt to go to the right than to the left. They are known to compress and occlude the right main bronchus or its main branches, and they may secondarily undergo late in their development the type of malignant change that it seems to me is suggested by the recent developments in this man's history. But unhappily for me, he never spit up any hair or teeth or had any of the other charming observations that serve to make a positive identification of such a tumor. However, it seems to me that that group—probably a dermoid cyst with malignant change—fits the bill better than any other type of tumor I can think of.

The commonest tumor, of course, to give this kind of termination is bronchiogenic carcinoma. Bronchiogenic carcinoma with an onset at twenty is not impossible, but one that lasts for seven years is certainly an extreme rarity. According to the statistics I could put my fingers on, the great majority of people with bronchiogenic carcinoma do not live for more than five years. In fact the

longest duration that I could find in recorded cases of bronchiogenic carcinoma was between five and six years.

There is one other point. This man had had attacks of palpitation. Whether these were because he was nervous, or because he was anemic, or whether these attacks were associated with paroxysms of tachycardia or fibrillation I do not know. Such paroxysms occur frequently in people with pulmonary or mediastinal carcinoma, or with actual invasion of the pericardium by carcinoma, and the record does suggest that these attacks may have been brought on by such a mechanism.

I shall conclude by saying that I believe this man had a pericardial effusion, pleural effusion and bronchial obstruction with atelectasis, and that this was based on an extramural neoplasm that eventually involved the walls of the bronchi. This tumor was originally benign but eventually underwent malignant change and extended to the pericardium. Of all types of neoplasm, I consider a dermoid cyst to be the likeliest origin.

When one thinks of pericardial obstruction or distention in a case of neoplasm, one has to consider the possibility that it is due not to fluid but to actual invasion of the pericardial cavity by solid tumor. I know only two ways to make the diagnosis: to find cells in the pericardial fluid, which is comforting, or to see a shadow of the pericardium that is not smooth but lumpy. That may be inflammatory, of course, but is likely to be tumor.

DR. BENJAMIN CASTLEMAN: Dr. Sweet, you said that the pericardium was tapped. Is that correct?

DR. RICHARD H. SWEET: Yes. The reason it is not in the record is that I did it myself and forgot to write it down.

I did a pericardial tap through the paraxiphoid region first and obtained fluid readily. But it looked to me to be whole blood, and after drawing off a few hundred cubic centimeters, I withdrew the needle because I did not want to bleed the man to death. At the suggestion of Dr. Conger Williams, who saw this man with me, I then inserted the needle laterally to the first tap and the same kind of fluid was obtained; I could feel the pulsation of the heart muscle with the needle. We were sure that he had a massive effusion. Since the fluid was so much like whole blood and since the patient had a red-cell count of 2,500,000, I desisted. At a later chest tap we also removed whole blood.

DR. BURWELL: If it was fluid blood,—and I think it must have been,—that strengthens the case for rapidly growing neoplastic invasion. The presence of blood in the pericardium is due either to trauma, to cardiac rupture or to neoplasm. The

inflammatory fluid from tuberculosis may contain red cells, but it is not usually grossly bloody.

What about his sputum?

DR. SWEET: The patient never had any hemoptysis. He had a lot of cough and Dr. Burwell was correct in his interpretation of the bouts of what the doctors called variously grippe, pneumonia or what not, which must have been due to bronchial obstruction. After the patient died I obtained a report from the surgeon who operated on him seven years previously. He was convinced that the pulmonary tumor was a carcinoma.

DR. BURWELL: Not a shriveled-up lobe?

DR. SWEET: No; he saw a large round mass.

DR. BURWELL: It was within the right lung?

DR. SWEET: Yes, in the region of the middle lobe. Unfortunately no biopsy specimen was taken.

I never entertained any thought of operating on the patient, but tried to establish a diagnosis. My conclusion was that he had a teratoma.

DR. BURWELL: No teeth could be seen in any of the x-ray films?

DR. SWEET: No; however, I do not mean a dermoid cyst. A teratoma behaves differently from most of the dermoid cysts in the mediastinum that I have seen.

DR. CASTLEMAN: I am sorry that Dr. Conger Williams is not here, but I shall read his note:

I am in favor of the diagnosis of pericardial effusion with tamponade to explain the findings of high venous pressure, paradoxical pulse and large cardiac shadow without evidence of valvular disease or anything to suggest diffuse myocardial involvement. Additional suggestive findings are left-border dullness 2 cm. outside the apparent apex impulse and narrowing of the border of superior cardiac dullness on the left in the sitting position in comparison with the lying position. There is probably some displacement of the heart shadow to the left, but it does not account for the large cardiac shadow. The blood pressure of 108/78 is not especially impressive, but does not exclude the diagnosis. The fact that the heart sounds come through well does not rule out pericardial effusion. Also in favor of pericardial effusion, as against heart failure, is the fact that the patient can lie flat on his right side without dyspnea.

CLINICAL DIAGNOSES

Teratoma of mediastinum, with extension to right bronchus and pericardium.
Pericardial effusion, with cardiac tamponade.

DR. BURWELL'S DIAGNOSES

Malignant dermoid cyst of mediastinum, with extension to right bronchus and pericardium.
Pericardial effusion, with cardiac tamponade.
Pulmonary atelectasis and bronchiectasis.
Pleural effusion.

ANATOMICAL DIAGNOSES

Carcinoma of the lung, with extension to pericardium, right auricle and pulmonary vein and partial obstruction to superior vena cava.

Pericarditis, acute and chronic, with hemorrhagic effusion.

Cardiac tamponade.

Pulmonary atelectasis, with cholesterosis, right middle lobe.

Hydrohemothorax, slight, right.

Pleuritis, chronic, fibrous, right.

ing bronchial obstruction. The middle and lower lobe bronchi were filled with tumor nodules. This tumor had extended medially to involve the right side of the pericardium, and the pericardial cavity contained a liter of bloody fluid. The visceral pericardium was covered with a shaggy brownish-red fibrinous exudate. The tumor apparently had extended through the wall of the parietal pericardium and had bled into the pericardial cavity. There was no actual tumor on the visceral layer, so that all this blood in the pericardial cavity was due to oozing from the tumor the

FIGURE 3 Photomicrograph of Tumor Invading the Myocardium of the Right Auricle.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: There was only about 100 cc. of hemorrhagic fluid in the right pleural cavity, but most of the cavity was obliterated by dense fibrous adhesions. Most of the right lung was replaced by a grayish-white granular, soft tumor with many areas of necrosis, one of which formed a cavity measuring about 3 cm. in diameter in the lower lobe. The tumor involved the entire lower lobe and the lower four fifths of the upper lobe. The middle lobe was entirely collapsed and fibrotic and was mottled yellowish orange, owing to the large deposits of cholesterol. This so-called "cholesterosis" of the lung is not uncommon with long-stand-

had penetrated through the parietal layer. It also penetrated through the right auricular wall into the auricle, obliterating a large part of the cavity, blocking the orifice of the superior vena cava, but without involving the endocardium. The tumor had also extended from the lung into the lower pulmonary vein for a distance of 4 cm. and had almost reached the left auricle. A photomicrograph (Fig. 3) taken through the right auricular wall shows tumor cells replacing myocardial fibers. The tumor cells are epithelial in character. There is no stroma between the cells and without knowing anything about the disease I am sure every pathologist would call this straightforward carcinoma of the lung. With the in-

mation that the tumor was of at least seven years' duration one might be justifiably skeptical of a diagnosis of carcinoma and might then bring up the diagnosis of endothelioma, possibly arising from the pleura.

DR. BURWELL: That would account for the extraordinary bleeding.

DR. CASTLEMAN: Most of the tumors of the pleura diagnosed as endothelioma are carcinomas of the lung with extension to the pleura. In fact we rarely if ever make the diagnosis of endothelioma. The cases that have been reported as endothelioma usually have nodules all over the pleura and are associated with a hemorrhagic effusion. There were no nodules on the pleura in this case. Another theory of the origin of this tumor is that it arose from a bronchial adenoma. The right bronchi were filled with tumor, which may have been benign years ago and then became malignant, as a few of them do. We know that adenomas are prone to extend through the bronchial wall and form large extrabronchial tumors. Perhaps the tumor felt seven years ago may have been an adenoma. If that were true, it is strange that the patient had no hemoptysis.

DR. BURWELL: That is what troubled me.

DR. CASTLEMAN: Nevertheless, I think we have to make a positive diagnosis at autopsy of carcinoma of the lung with extension into the pericardial cavity and into the heart. There was a metastasis to an intrapulmonary lymph node, close to the tumor, but no distant metastases.

DR. J. H. MEANS: Would you grade it as a slowly growing malignant tumor because it has been there for seven years? It must have been growing slowly.

DR. CASTLEMAN: It was not rapidly growing, but certainly not slowly growing.

DR. BURWELL: Is that not an extraordinary duration?

DR. MEANS: It does not seem possible that a carcinoma of the lung could have been present for seven years.

DR. CASTLEMAN: I was also puzzled and showed these slides to two other pathologists, who agreed to the diagnosis of carcinoma.

DR. BURWELL: Suppose it had been an adenoma. Might it not have developed deep enough in the mucosa so that it went outward instead of inward?

DR. CASTLEMAN: All the adenomas with extrabronchial extension that we have seen also have a nodule of tumor protruding into the lumen, unless, of course, it had been removed bronchoscopically.

DR. BURWELL: It seems to me evident that whatever this was seven years ago, it was a carcinoma

at autopsy. The problem that has to be settled is the presence of an obstructing lesion seven years previously that eventuated into a carcinoma of the lung.

DR. CASTLEMAN: I believe that one can have a carcinoma of the lung of low-grade malignancy for seven years. A case that Dr. Allen discussed recently was a hepatoma of nine years' duration.* I think the whole idea of long-standing malignant tumors is something that we perhaps do not appreciate sufficiently.

DR. BURWELL: He had no hemoptysis.

DR. SWEET: No, which suggests that the tumor did not arise in a large bronchus.

DR. BURWELL: That is one of the reasons why I thought of an extramural source.

DR. SWEET: I was convinced all along, until I saw the autopsy, of mediastinal origin.

CASE 29342

PRESENTATION OF CASE

A twenty-nine-year-old housewife entered the hospital because of sharp pain in the right hip that radiated down the right leg.

Approximately five months prior to admission, without previous trauma, she developed sharp pain in the right hip that radiated down the right leg to the foot. At first this was mild and sporadic but during the previous four months the pain had occurred daily, had interfered with walking and had often kept her awake at night. On several occasions the right foot felt slightly numb and there were "pins and needles" in the foot. About three months prior to admission the pain became so constant and severe that she did not dare leave the house for fear that she would collapse. Five weeks before entry she fell down three stone steps, landing on her left side. After this her back was constantly sore.

Physical examination disclosed a thin woman who seemed comfortable. She walked with a slight tendency to favor the right leg. The pelvis was held level, but there were moderate lumbar lordosis and slight dorsal kyphosis, and the weight-bearing axis seemed displaced posteriorly. Examination of the heart and lungs was negative. In the right lower quadrant of the abdomen was a 1 by 2 cm. area of pigmentation suggestive of a "café-au-lait spot." There was no tenderness over the spinous processes. There was questionable fullness in the right iliac fossa, and slight tenderness to deep palpation in the right pelvic fossa, but no mass was felt. There was no pain

*Case records of the Massachusetts General Hospital (Case 29331). *New Eng J Med* 225: 347-348, 1941.

on compression of the pelvic brims. Straight leg-raising on the right was limited to 75° because of tightness in the hip. However, there was a full range of hip and knee motion with the leg flexed.

The blood pressure was 95 systolic, 60 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood revealed a red-cell

showed slight enlargement. The cortex appeared normal. The remainder of the visible skeleton showed no evidence of decalcification. No abnormal soft-tissue masses were seen. The pelvis was slightly tilted to the left. Films of the right lower femur and of the upper part of the lower right leg showed no evidence of bone pathology. Films of the chest were negative. An

FIGURE 1. *Roentgenogram of the Right Ilium.*

count of 4,280,000, with a hemoglobin of 80 per cent, and a white-cell count of 6300. The urine was negative except for a ++ Sulkowitch test for calcium. A blood Hinton test was negative. The serum calcium was 10.5 mg.; the phosphorus 3.0 mg., and the phosphatase 5.1 Bodansky units per 100 cc.

Stereoscopic x-rays films of the pelvis revealed a multilocular cystic defect with sharply defined borders extending from the crest of the right ilium to the acetabulum (Fig. 1). The bones involved

intravenous pyelogram showed no evidence of renal pathology; the right ureter was slightly displaced medially in its lower portion, probably by the mass in the right ilium.

An operation was performed on the twelfth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. FREDERIC W. RHINELANDER: We have a twenty-nine-year-old woman with a large multilocular cystic area in the ilium and pain of five

months' duration, which had become very severe at the end. Certain points in the history can be taken as probably being significant. The radiation of the pain down the leg is compatible with sciatica, which suggests a lesion in the region of the pelvis rather than one in the hip itself. The fact that the pain was worse at night is also suggestive of bone pain. The fact that the pain became so extremely severe is rather characteristic of tumor. The roentgen report states that the patient had a large lesion in the ilium. Thus, so far, everything in the history fits in.

She is said to have been a thin woman. There is no mention of weight loss, which, had it been a prominent feature, would probably have been put in the history. The displacement of the weight-bearing axis posteriorly is simply what one would expect with poor posture, and is not significant. The mass was palpable, probably deep in the left lower quadrant, which goes with the x-ray picture of something involving the right ilium. The "café-au-lait spot" was apparently a single pigmented area, which I shall discuss later. The fact that there was no pain on compression of the pelvic brim—that test is done to see if there is involvement of one of the joints of the pelvis—suggests that the lesion did not involve these joints. Straight leg-raising was somewhat limited, indicating tightness in the hamstrings, which goes with any lesion in this area that produces muscle spasm and has no diagnostic significance so far as we are concerned.

The blood picture is normal and does not help. A ++ Sulkowitch test is not significant unless the patient is on a low-calcium diet. This is not mentioned here, so probably that was not done. The Hinton test was negative, and the blood calcium and phosphorus were normal. The phosphatase was at the upper level of normal, or a little bit over by most standards; but with an extensive bone lesion, such as we see here, it would probably be considered normal.

May we see the x-ray films?

DR. MILFORD SCHULZ: This is the cystic lesion. It does not appear to expand the bone markedly and does not involve the hip joint. It is multilocular. There is no place where the cortex seems to be broken through. The edges are quite sharply defined. There is not much reaction of the bone at the periphery of the cystic lesion. I think that one would be quite safe in saying that it is a benign lesion. There are no other apparent lesions in the bone. As the record states, there is no decalcification, which tends to rule out a systemic disease that gives cystic changes in the bone. I do not know whether we can accept the displacement of

the ureter as having anything to do with the lesion in the hip.

DR. WILLIAM B. BREED: Did I understand you to say that the ureter was displaced?

DR. SCHULZ: It is displaced medially at the brim of the pelvis.

DR. RHINELANDER: When these films are put in the stereoscope, one can see large cystic areas that, except for a little area at the wing, extend throughout the ilium.

Concerning the differential diagnosis, the most likely conditions are benign bone cyst, enchondroma, eosinophilic granuloma and giant-cell tumor. The others that should be mentioned are easy to rule out, and we can then come back to the more important ones. There is certainly no evidence of malignant disease. This is a large tumor, with a smooth surface and intact cortex. There is no evidence of infection in the clinical picture or the history. A gumma can occur in this area, but the Hinton test was negative and the x-ray films do not suggest it. Albright's disease¹ was probably thought of when the pigmented area was noted, but there is nothing in the picture to suggest that. The lesion was single and there is no mention of sexual precocity, which probably would have been brought out if that had been a serious consideration. Von Recklinghausen's disease of bone (generalized osteitis fibrosa cystica) is ruled out by the single lesion and by the normal blood calcium and phosphorus.

The age of the patient is against a benign bone cyst (localized osteitis fibrosa cystica). In this disease, most patients are under fifteen, and when it does occur in adults, it is usually a case of long standing that had not been discovered in early life, which is quite compatible with this story. Although pain is an uncommon symptom in benign bone cyst, in cases in which the lesion is so large, considerable pain may be expected. That is compatible with this patient's story of no pain in childhood. Pain may not be noticed in a deep-seated bone where there is not much function going on. The site is distinctly unusual for a benign bone cyst, which usually occurs in the shaft of one of the long bones.

The age of the patient is also against enchondroma, which is generally found in the phalanges; but that has to be considered. A multilocular cyst goes with either benign bone cyst or enchondroma.

Eosinophilic granuloma is distinctly uncommon in adults but it has been reported. The location, however, is rather characteristic. However, the large loculi and the integrity of the cortex in a tumor of obviously long duration are very much against this diagnosis, as they are against enchondroma.

The age goes with giant-cell tumor. The severity of pain is suggestive of this condition, but such a tumor occurs at the epiphyseal ends of the long bones, which rather effectively rules this out.

This is obviously an unusual condition. It does not fit in well with any of the lesions mentioned. It is in an unusual location. I think that it corresponds more with a benign bone cyst than with any of the other conditions. The large loculations that one can see in the stereoscope have the appearance of being empty; there is no evidence of cancellous structure, just the big loculi. The fact that the disease had been going on obviously for a great many years takes it back into the age group of benign bone cyst. It was probably present in childhood, when it was painless, and then reached a stage where it expanded the cortex somewhat. That is compatible with this condition, perhaps more so than with the others I have mentioned. Therefore I shall say that the most likely diagnosis is an extensive, localized, benign bone cyst.

DR. FULLER ALBRIGHT: I should like to vote for enchondroma. It looks much like another case that we have had recently.

CLINICAL DIAGNOSIS

Enchondroma or benign giant-cell tumor of ilium.

DR. RHINELANDER'S DIAGNOSIS

Benign bone cyst of ilium (osteitis fibrosa cystica localisata).

ANATOMICAL DIAGNOSIS

Fibrous dysplasia of ilium.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The lesion at operation was found to be cystic, and at biopsy, the wall of one of the cysts and the cortex showed dense fibrous tissue in which there were many bone spicules and areas of imperfectly calcified bone. The ap-

pearance is characteristic of what has been described by Lichtenstein and Jaffe² as fibrous dysplasia of bone. This is a condition that may affect one or several bones; it is usually unilateral and is believed to be a congenital maldevelopment of the bone-forming mesenchyme. Occasionally degeneration with cyst formation of this fibrous tissue occurs, and that is what probably happened in this case. It is the same condition that Albright¹ has called osteitis fibrosa disseminata, but is limited to one bone. I prefer the term fibrous dysplasia because it indicates both the pathologic anatomy and the etiology and because it lessens the confusion with von Recklinghausen's disease of bone (osteitis fibrosa cystica generalisata).

DR. ALBRIGHT: Then you would call it a bone cyst?

DR. CASTLEMAN: It all depends on what you mean by bone cyst. The term "bone cyst" usually applies to a single-chambered cavity occurring in the shaft of a long bone, close to the epiphysis. Other bone lesions, such as the osteitis fibrosa cystica associated with hyperparathyroidism, fibrous dysplasia and giant-cell tumor, may have cystic changes, but the fundamental condition is not a cyst.

DR. ERNEST M. DALAND: What is the prognosis and treatment?

DR. ALBRIGHT: Very good, I should say. The treatment is symptomatic. When it involves a long bone the treatment is that of giant-cell tumor. You curette out the tumor and fill it with bone chips.

DR. DALAND: There is a difference of opinion about filling with bone chips. We believe that it is unnecessary.

"— OR ELSE"

The action implied by two words, "or else," uttered by Mr. Paul V. McNutt at the annual meeting of the American Medical Association in 1942 is apparently about to be taken by the Selective Service System to support the increasing demands of the War Manpower Commission. Married men with families who were engaged in nonessential industries have been inducted into military service, and it seems likely that the physician with dependents who has been declared "available" will be treated in a like manner. In fact, according to an editorial in the August 7 issue of the *Journal of the American Medical Association*, a directive has al-

ready gone to the commanding officers of the various service commands authorizing them, if necessary, to induct into service all such physicians between the ages of thirty-eight and forty-five.

The editorial goes on to state that the increasing tempo of the war effort necessitates an additional six thousand physicians in the armed forces by January 1, 1944. The need for these officers is acknowledged by the War Participation Committee of the American Medical Association and by the Procurement and Assignment Service. Indeed, it is so real that the status of physicians already declared "essential" will probably be reviewed to obtain from civilian life all those who can be spared.

The *Journal* has always asserted—possibly somewhat optimistically—that induction of physicians would never be necessary. If its faith in members of the medical profession is to be maintained, each physician who has been declared "available" and who has failed to offer his services must reappraise his position with a view to enlisting. If he waits for induction, it is likely that his eventual commission will be minimal, rather than according to his age and experience. Because of the need and because of the traditional patriotic response of physicians at such times, there still seem to be reasonable grounds for believing that "— or else" will be unnecessary.

THE DOCTOR PRESCRIBES A DIET

Just as the medical practitioner must be versatile, treating his patients for their real and apparent illnesses, advising them in misfortune and comforting them in affliction, procuring for them extra fuel oil in the winter and extra gasoline in the summer and prescribing for them additional allowances of rationed foods because of their varied appetites, idiosyncrasies and infirmities, so must he also be independent in thought and action, bold in diagnosis and original in treatment.

Nowhere can these latter virtues be more strikingly illustrated than in the prescription of diets, and never has the diet been a source of greater interest than in these days of apportioned food

supplies, of ration books and of red points and blue points. To the physician, as is his due, has been given the responsibility of prescribing foods for persons over and above the amounts allotted after careful studies of the available supplies with the knowledge that, when a limited amount is available, that which is given to one above his allotment must, in theory at least, be taken away from the rest.

The number of extra diets thus prescribed has been not inconsiderable; and although many of these requests can be granted out of hand by local rationing boards, when any question seems to exist concerning the propriety of a request, it is referred to the district branch of the Office of Price Administration. Here, if a doubt still lingers,—and, believe it or not, this office is discharging its difficult and thankless function of food rationing in a fair and intelligent manner,—the matter is referred to an advisory committee of physicians appointed for this purpose by the Council of the Massachusetts Medical Society.

During the last two months well over two hundred such requests have been reviewed by the Boston branch alone, and they illustrate beautifully the independence of thought and freedom from the bonds of tradition that the medical profession enjoys. For one patient, for instance, with duodenal ulcer, 40 pounds of processed foods per month, with no extra meats and fats, were prescribed; for another with the same disease, no extra processed foods, but 56 pounds of meats and fats were required. How true the old saying that one man's meat may be another man's poison! For a patient with gastric ulcer, 15 pounds of processed foods and no meats and fats were requested; for another, 48 pounds of processed foods and 83 of meats and fats for a month's allowance. A patient with hypertension and cerebral anemia apparently requires 180 pounds of processed foods and 55 of meats and fats for the lunar period, and one with partial hemiplegia, 143 pounds of meats and fats alone. Let us hope that the last stricken gourmand will have a butcher's

assistance in carving his daily 4 pounds or so of porterhouse! A patient with gall-bladder disease, however, should receive the laurel wreath for his ability to assimilate 10 pounds per day, or 600 for a two-month period, of processed foods—practically enough to stock a small grocery store.

Processed foods—mainly fruit juices and canned, frozen and dried fruits and vegetables—actually present more of an economic and educational problem than they do a medical one. Meat, cheese and fats, most of which are rationed whether processed or not, are protective foods of greater vital importance. With a clear understanding of the value of such unrationed protein as fish, poultry, milk and eggs, however, it becomes apparent that the generally accepted popular values placed on the red meats are large esthetic ones.

A general discussion of diet and disease is beside the point. It should be emphasized, nevertheless, that if a reasonable degree of care is spent in apportioning ration points, few patients, regardless of their illnesses, require much in the way of food that their basic rations, together with the unrationed foods available, do not supply. For more detailed practical information the reader is referred to the article by Dr. Stare¹ and the letter of Dr. McLaughlin² in recent issues of the *Journal*.

Physicians, of course, will be besieged by seekers of special privileges. If such privileges are granted too liberally, however, and without particular knowledge of the circumstances, they will simply allow themselves to become the dupes of the patriotic, the self-indulgent and the unscrupulous.

MEDICAL EPONYM

BITOT SPOTS

The true nature of these spots as indications of vitamin deficiency was unknown to their original describer, Pierre A. Bitot (b. 1822), professor of anatomy at the School of Medicine and honorary

surgeon of the Bordeaux hospitals, who published in article, entitled "Mémoire sur une lésion conjonctivale non encore décrite, coïncidant avec l'héméralopie [Account of a Conjunctival Lesion not Previously Described, Coincident with Hemeralopia] in the *Gazette Hebdomadaire de médecine et de chirurgie* (10:284-288, 1863), in which he reported 25 cases. A portion of the translation follows:

The purpose of the present note is to point out . . . the coincidence of hemeralopia with a lesion of the conjunctiva; but this lesion does not involve the region of the pupils, forming rather on the eyeball, and consists not in an inflammation but in a collection of brilliant white points which produces what resembles a pearly or silvered spot at the side of the transparent cornea.

This coincidence has neither been described nor even pointed out in the literature.

RESOLUTIONS

RESOLUTION ON THE DEATH OF ROBERT TITUS PHILLIPS

The recently reported death in a Japanese prison camp in the Philippines of Major Robert T. Phillips, M.C., A.U.S., at the age of forty-one, came as a distinct shock to his many conferees and friends in New England.

To know "Bob" Phillips was to admire him and cultivate his friendship. Graduating from Tufts College Medical School in 1932 he served as house officer and resident on the Third Medical Service at the Boston City Hospital from July, 1932, to February, 1935, and was appointed junior visiting physician to the Boston City Hospital in December, 1936, resigning in August, 1938 when he left Boston to practice his chosen specialty in Portland.

From his college days he displayed unusual executive ability. When a student at Tufts he founded the William Harvey Society, an organization that has perpetuated his ideals and has provided for Tufts medical students, for more than a decade, lectures and seminars at regular intervals, given by national figures in medicine. He was secretary of the Tufts College Medical School Alumni for many years and was a stimulating influence in the reorganization and development of that body.

As a physician he was especially interested in arthritis and was a member of many medical societies. He was commissioned a lieutenant in the Medical Corps Reserve in December, 1922 and

was called to active duty about six months before Pearl Harbor, being in the Philippines when war was declared. The last word from him was received by his wife on January 6, 1942, and told of the evacuation of Manila. Major Phillips wrote that he expected to go to Bataan, where he was taken prisoner. His parents, widow and four children survive him.

Be it resolved that the members of the Boston City Hospital hereby express their regret at the loss of a former beloved member of the Staff and extend to the members of his family their sincere sympathy.

WALTER T. GARFIELD, *Secretary*
Executive Committee
Boston City Hospital

RESOLUTION ON THE DEATH OF CHARLES MACFIE CAMPBELL

We, the Trustees of the Boston Psychopathic Hospital, hereby record our deepest appreciation of the fine leadership which Dr. Charles Macfie Campbell has given unflinchingly for the good of our hospital service during the last twenty-three years. We have had a continuing opportunity to recognize and to value his admirable professional and personal qualities, and we have been proud of the many national distinctions which he has attained.

Our sense of loss, moreover, includes the poignant realization that a good comrade has passed from us.

We extend our heartfelt sympathy to the family of Dr. Campbell.

CORRESPONDENCE

SPECIALISM

To the Editor: It has been called to my attention that, in an article entitled "The Universality of a Specialty," which was read before a student medical society in December, 1942, and published in the June 3 issue of the *Journal*, my statement that "the officer-of-the-day . . . though trained as an allergist or ophthalmologist must

nevertheless operate on any patient with an acute appendix who is admitted to the hospital at night during his tour of duty," is not in accordance with the present practice in the Army or Navy. I am informed that the officer-of-the-day acts in the same way that a surgical resident docs. He sees all cases that are admitted to the hospital during his tour of duty and decides as to their disposition within the hospital. He can, if he wishes to do so, subject to the customs and orders peculiar to his own hospital and if such treatment is called for, operate on the case himself, call any other member of the staff in consultation or refer the case to any other member of the staff for operation by the latter officer. In the armed services, just as in civilian hospitals, the majority of residents exercise their prerogatives properly and with proper regard for the well-being and safety of the patients. That such proper regard is not always present in the armed forces any more than it is in civil life is evidenced by the illustrations cited above (which actually happened) and by many other similar instances of errors of commission or omission.

Despite the impropriety of my illustration, I see no reason to alter my conviction—as certain critics have suggested I should—that fundamentally the attitude of the medical department of the armed services is one which, as I stated, "still visualizes the general surgeon as a general specialist." This has to be and is properly so under combat conditions but should and need not be so in this country. In relation to neurosurgery in the Army it has been pointed out that sixteen hospitals have been designated by the Surgeon General as specialized hospitals for the treatment of such conditions. This does not mean that these hospitals receive only neurosurgical cases or that they are staffed exclusively by neurosurgeons. It does mean that somewhat more of the usual equipment and staff than exists in the ordinary general hospital has been made available for this specialty in these locations. Where large numbers of neurosurgical patients are concentrated and where the work is done under the direction of a man who has specialized in neurosurgery in civilian life,—as, for example, in the clinic at the Walter Reed Hospital,—no clinic in civil life can surpass and few can equal the calibre of care provided for such patients. There, the neurosurgeon does neurosurgery and nothing else. In other less active centers, however, this is not so. The neurosurgeon is expected to fill in as a general surgeon when there is nothing to do in his own department. Differences in technic, outlook and training in surgery as opposed to neurosurgery are disregarded. The patient whose abdomen would have been opened and closed in a half hour by the nonspecialist is endangered by the fact that the neurosurgeon, who is trained to a painstaking "puttering" type of operating, takes two hours to do the same thing. On the other hand, the general specialist who approaches a craniotomy in terms of a laparotomy will—as has occurred—lose his patient because of bleeding he has neither the patience nor the knowledge to stop or from postoperative surgical shock or circulatory collapse induced by his mistaken belief in the virtues of speed in operating.

A method of handling neurosurgical patients based on the assumption that a neurosurgeon should be able to act at will either as a competent general or as an equally competent specialized surgeon is, I submit, evidence of the conviction—not of junior officers of the medical de-

partments but of those who make the governing policies of the departments—that general specialism as I have described it in my article is a good thing. Whether that is true or not is a matter of opinion that each reader will decide for himself.

BOOK REVIEWS

Lymph Node Metastases: Incidence and surgical treatment in neoplastic disease. By Grantley W. Taylor, M.D., and Ira T. Nathanson, M.D. With a foreword by Shields Warren, M.D. 8°, cloth, 498 pp., with 61 illustrations and 117 tables. London: Oxford University Press, 1942. \$3.00.

This is the first book of its kind to be published. The authors are to be commended for assembling a vast amount of information on the subject from the literature, for collecting data from three hospitals treating large numbers of cancer patients and for analyzing the results in such a way that proper conclusions can be made of the correct way to deal with metastasizing cancer.

The cases studied are from the Massachusetts General Hospital, the Collis P. Huntington Hospital and the Pondville Hospital (Massachusetts Department of Public Health). The authors are on the staffs of these hospitals and have participated in many of the operations on which they base their conclusions. During recent years, when this book has been in preparation, they have made detailed studies of the anatomic structures concerned in the dissections, the exact location of the nodes and the best types of incisions for each operation. Excellent drawings have been made of these dissections, and the reader may be assured that those shown are true representations of what was found and done at operation. The set-up of the book is pleasing and the subject matter is well arranged.

Part I deals with the anatomy of the lymphatic drainage areas. It is important to know the course of lymph drainage from various organs, the location of lymph nodes and the mechanism of lymph-node metastasis. Certain types of carcinoma are prone to spread along these channels. If the cancer is to be cured, the local process must be destroyed and the regional nodes must be removed. Again, if a metastatic node is palpated, a proper knowledge of lymph-node metastases allows the surgeon to search back for the primary focus. The various body regions have been studied for the exact location of lymph nodes. They are discussed in groups, such as the occipital nodes, the mastoid nodes and so forth, and their relation in the chain of nodes is brought out. Diagrammatic drawings of these lymph nodes in situ, the nodes numbered according to a key and the anatomic structures marked by legends on the side, are very effective. Lymph nodes of the head, neck, axilla, groin, pelvis, abdomen and thorax are demonstrated.

The regional surgical management of lymph-node metastases is the subject of Part II, in which 5481 cases of cancer are analyzed. In 48 per cent, lymph-node metastases were present. Careful study of these cases in groups is the basis for the conclusions and policies regarding treatment.

Lymph nodes may harbor metastases for some time before they become palpable. There is no close correlation between palpability of nodes and involvement by metastases, particularly when the nodes are small. When dealing with carcinomas of relatively low incidence of metastases, small palpable lymph nodes may be of no significance, however, with carcinomas known to metastasize early and widely, small nodes are of great significance. Nodes of more than a centimeter in diameter are quite likely to show metastases. If nodes are firm in consistency, metastases are likely to be present, although inflammatory or tuberculous nodes may be hard. Extension of the growth through the capsule of the node with resulting fixation usually indicates inoperability.

The time at which dissection is done influences the curability of node metastases. If block dissection can be done at the time of removal of the primary tumor, as in the breast, this is the preferable method. In some cases, such as those of the lip, dissection of the neck should be done as soon as the primary lesion has been treated and the wound healed. Dissection of nodes present for a long time or occurring some time after the removal of the primary lesion gives a much poorer prognosis than if early dissection is done. Prophylactic dissection may be advised even though no nodes are palpable, but the decision rests chiefly on the type of primary lesion.

The writers are skeptical of the value of prophylactic radiation of lymph nodes. They state, "It has not been demonstrated that such treatment prevents or diminishes or defers the occurrence of metastases." Preoperative radiation does, however, interfere with the healing of the operative wound. It is sometimes advocated on the basis of destroying cells spilled at operation, but if the case is properly selected and if adequate operation is carried out there rarely is a recurrence in the operative field. If disease is left behind, radiation should be used; but if not, radiation should be reserved until recurrence takes place. Then sufficient treatment should be given to destroy the lesion.

Operations on lymph node areas are described in Part III. Regional dissection of nodes is not advocated unless the primary lesion has been or can be cured. Fixation of nodes and widespread involvement are usually considered as contraindications to operation. The patient should be carefully prepared for surgery; deficiencies should be corrected and the operation should be done only when he is in the best possible condition. Block dissections should be carried out with great care. Sharp dissection should be used, with fine silk for ligatures. All serum and air should be expressed from the wounds, and pressure dressings should be applied. Most wounds are drained.

Supraomohyoid dissection is advocated for metastases from lesions of the lip and buccal mucosa and the skin of the central third of the face. The platysma muscle is always removed. The operative mortality among 601 patients in three hospitals was 15 per cent.

Radical neck dissection, with removal of all nodes down to the clavicle, the internal jugular vein and the sternomastoid muscle, as well as all tissues removed in the supraomohyoid dissection, is recommended for metastases from the tongue, floor of mouth and parotid gland. The mortality among 112 patients was 36 per cent.

Axillary dissections are done as part of the routine operation for carcinoma of the breast and for metastases from the arm or upper portion of the trunk. In breast operations, removal of the pectoral muscles is essential

to gain access to the nodes of the upper axilla. When the lesion is on the extremity, transection of the pectoralis major is performed and the inner portion is left on the chest wall. The operative mortality among 1153 patients with carcinoma of the breast was 23 per cent, and that of patients undergoing axillary dissections for other lesions was nearly the same.

Inguinal dissections are advocated for malignant lesions of the lower extremities and for metastases from the anus, perineum and external genitals. Simple dissection is often sufficient if the primary lesion is on the extremity. Radical dissection, with removal of the fat and lymphatics along the external iliacs, is necessary for lesions on the anus or genitals. The operative mortality among 262 patients was 38 per cent. In nearly all the deaths, bilateral dissection was done in one sitting, and in several cases the primary lesion was excised at the same time. The authors advise that operations be done in three stages.

The entire book is well done and fills a very important place in cancer literature.

The Essentials of Emergency Treatment 8", cloth, 146 pp. New Haven, Conn. Connecticut State Medical Journal, 1942.

The value of this little book to physicians who may be called on to do emergency practice should be great. If it were used by all chief medical officers in the Emergency Medical Service of the Office of Civilian Defense it would certainly be instrumental not only in reducing pain and infection but also in saving lives.

Throughout its chapters, surgical essentials are so clearly and simply presented that the volume is most readable, and the reviewer even ventures to add that it will provide an enjoyable evening's reading by the fireside with one's feet up and the favorite pipe functioning satisfactorily. This is no attempt at levity, but an emphasis of the way in which the material on complex subjects has been presented, without being weighted down by forbidding ultrascientific data.

It is difficult to pick out any one chapter as being better or more instructive than another—each chapter is in itself so worthwhile reading and digesting. The complexity of wound healing, shock and burns, for example, is presented simply and clearly. One does not have to be a professor of chemotherapy to understand it.

One statement, which now is erroneous, deserves comment. On page 56, in the chapter on burns, the author is discouraged at the lack of civilian plans for the storing of blood plasma. This section was written early in 1942 and at that time little had been done to provide adequate amounts of plasma for civilian use. Now, through the efforts of the Office of Civilian Defense and the United States Public Health Service, sufficient stores of plasma are available throughout the country for any civilian needs that might arise. Certain hospitals have been and are collecting, processing and storing plasma and are distributing their surplus to other hospitals. The Office of Civilian Defense has also allocated many units of plasma to strategic communities.

The authors have done a great service to the medical profession in collaborating in this series of papers. The book should be on the desk—not on the shelf—of every practicing physician, and much of the factual material should be constantly kept in mind. The Connecticut State Medical Journal is to be highly commended for making this material so readily available to the profession.

Human Pathology. By Howard T. Karsner, M.D. Sixth edition. 4°, cloth, 817 pp., with 460 illustrations in black and white and 24 subjects in color on 16 plates. Philadelphia: J. B. Lippincott Company, 1942. \$10.00.

The sixth edition of Karsner's textbook has appeared approximately at the same time as the seventh edition of W. G. MacCallum's textbook and the fifth edition of Sir Robert Muir's textbook.

In spite of the fact that Karsner's book is shorter than that of MacCallum and that it does not go so deeply into the details of descriptive pathology as does Muir's book, it is in many respects equal to either. It deserves to be recognized as one of the three standard works in pathology of our time. Its especially valuable feature is the bibliography at the end of each chapter. There is evidence of profound knowledge and excellent choice, valuable not only for the beginner but for the mature pathologist. In many respects Karsner's book is a bonanza, demonstrating the wide experience, the close observation and the sound judgment of the author. Two good examples of this are the discussion covering the persistence of cartilage discs between the vertebrae in cases of pulsating and excavating aneurysms of the aorta and that regarding the reactivation of latent syphilis by the intercurrent of acute infections.

But it is the duty of a reviewer to find some grounds for adverse criticism. It would seem better to consider infectious monocyctosis in the chapter on infectious diseases than with the diseases of the reticuloendothelial system. If the heterophile antibodies are mentioned, their interference with the Wassermann reaction by giving a nonspecific positive should be mentioned. Although undulant fever is one of the diseases rarely seen by the pathologist at autopsy and although but few references to autopsy findings are found in the literature, it deserves mention in a textbook of pathology. In the chapter on glanders, since testicular foci are practically pathognomonic, they should be mentioned, especially because the edema of the seminal cord in infected animals is cited by the author. Agenesis of the kidneys is not limited to monstrosities.

In general, it may be said, that the sixth edition deserves to acquire new friends among students and doctors. For coming editions one might suggest a more elaborate description of certain aspects of pathology, for example, the biologic and structural peculiarities of infancy and old age.

The Dynamic State of Body Constituents. By Rudolf Schoenheimer, M.D. 8°, cloth, 78 pp., with 16 tables. Cambridge: Harvard University Press, 1942. \$1.75.

In considering reactions taking place within the living body, many substances long held to be relatively stable have been shown of late to be subject to reversible equilibria. Schoenheimer has characterized this situation as "a steady state of rapid flux."

Much of the experimental work leading to this radically new concept has made use of isotopically labeled compounds. Schoenheimer, a leading experimenter with the stable isotopes, summarized the most critical of his experiments and the sequential physiologic conclusions for the Dunham Lectures of October, 1941. The majority of the experiments utilize food stuffs (fats or amino acids) or metabolic intermediates (arginine or creatine) marked with introduced isotopes of hydrogen or nitrogen. Some few of the studies are startling in their simplicity. Fast-

ing rats were, for example, injected with heavy water, and deuterium was found in all the amino acid fractions, except lysine, isolated from the animal's proteins twenty-four hours after the injection. For the details of the more complicated studies the original book should be consulted. The activity of glutamic acid in reversible dehydrogenations and in transaminations is repeatedly emphasized.

Death intervened before the lectures were delivered; Dr. Schoenheimer's colleagues completed the necessary revisions. Dr. Hans T. Clarke presented the lectures, which appear in this small volume.

Psychiatry in Medical Education. By Franklin G. Ebaugh, M.D., and Charles A. Rymer, M.D. 8°, cloth, 643 pp., with 16 tables and 7 charts. New York: The Commonwealth Fund, 1942. \$3.50.

The authors have made a complete survey of the teaching of psychiatry in medical schools in this country, both to undergraduates and postgraduates. They have also examined the teaching facilities in general as well as special hospitals. The various methods of teaching are analyzed. A marked variation in methods of instruction in colleges and hospitals was found; no uniform agreement in regard to how psychiatry ought to be taught exists. Some schools give reasonably satisfactory courses, but in many the instruction is poor and inferior. Since psychiatric teaching is in a confused and unsatisfactory state, the needs for this survey are clearly indicated. Emphasis is rightfully put on the value of personality studies and the treatment of the whole patient—a total person with a mind as well as a body.

For the teacher of psychiatry, there is important material in the appendices to this book. The "personality study" used at the Johns Hopkins University School of Medicine and elsewhere is given in full. An outline of lectures in psychiatry and a list of central agencies for the direction of state institutions will also be found useful.

The book, in general, is adequate in every respect. From its use should come important advances in the teaching of psychiatry in the United States and elsewhere.

Ovarian Tumors. By Samuel H. Geist, M.D. 8°, cloth, 527 pp., with 312 illustrations. New York: Paul B. Hoeber, Incorporated, 1942. \$10.50.

This monograph is a thorough résumé of knowledge of ovarian tumors up to 1936. The embryology, anatomy and physiology are considered in some detail. There follows a discussion of each group of ovarian tumors represented in the classifications of Pfannenstiel, Sternberg, Goodall and Meyer. The references, which are many, include practically all the foreign articles on the subject but few references to American reports or investigations.

The book lacks an adequate discussion of the laboratory findings in cases of endocrine tumors of the ovaries, such as, reports of 17-ketosteroid and follicle-stimulating-hormone determinations, reports of the amount of estrin in the fluid of follicle cysts and so forth. There is some discussion of the problem, however, in the section on granulosa-cell tumors of the ovary.

This book is a satisfactory review of Dr. Geist's vast experience and of the foreign literature and, as such, is a valuable addition to knowledge of the ovarian neoplasms.

NUMBER 10

THE DIFFERENTIAL DIAGNOSIS OF CHRONIC BRIGHT'S DISEASE*

A Clinicopathological Correlation

JAMES S. MANSFIELD, M.D.,† G. KENNETH MALLORY, M.D.,‡ AND LAURENCE B. ELLIS, M.D.§

BOSTON

IT IS quite apparent to clinicians that the task of correctly foretelling the pathological findings in cases of advanced renal disease is difficult and may be impossible, since the end results of many types of renal disease may be similar so far as the clinical picture is concerned. Although much work on renal physiology and pathology has been reported in recent years, the studies that have approached the problem from the viewpoint of the clinician faced by a patient with hypertension and failing renal function are few in number, and those that have been made have for the most part paid little attention to chronic or healed pyelonephritis as an important type of chronic Bright's disease.

There exists, moreover, considerable confusion in the clinical and pathological nomenclature of Bright's disease, largely owing to the many different classifications of nephritis that have been in use. To some extent this is, as Christian¹ states, "more a matter of difference in words than in concepts." It is for the most part agreed that in one group vascular lesions predominate; in a second, diffuse inflammatory glomerular lesions are chiefly present; whereas in a third, degenerative changes in tubules and glomeruli are the outstanding features. A fourth type, however, also exists in which the lesions are mainly interstitial and originally infectious. Within recent years it has been shown and emphasized by Longcope and Winkenwerder,^{2,3} Peters, Laviettes and Zimmerman,⁴ Butler⁵

Weiss and Parker⁶ and others that renal infection—that is, pyelonephritis—may ultimately result in hypertension, often of the malignant type, as well as in renal failure. These late sequelae may occur even when the original infection has subsided and healing has taken place.

The pathological findings as well as the clinical manifestations of the various types of Bright's disease have been described on numerous occasions,^{1-4, 6-14} and no attempt will be made here to summarize the literature. Brief comment is, however, called for on the term "malignant hypertension," about which much confusion exists. As originally applied by Fahr,¹⁰ "malignant nephrosclerosis" was the pathological description of the kidneys of patients dying of uremia in which hyperplastic endarteritis and necrotizing arteriolitis were present. Later the problem was approached primarily from the clinical angle, and Keith, Wagener and Kernohan¹⁵ applied the designation "malignant hypertension" to a syndrome of severe hypertension with retinitis and papilledema, progressing rapidly to a fatal termination. Although many such patients died in uremia, some succumbed to cardiac failure or cerebral accident. The latter cases usually exhibited pathologically the same general type of renal lesion as that described by Fahr, but often to a less severe extent than those in which death was primarily due to renal failure.

It has been subsequently shown that malignant hypertension as seen clinically does not represent a single pathologic entity, but may occur as the terminal phase of benign essential hypertension, chronic glomerulonephritis or healed or chronic pyelonephritis, as well as rarely in conditions such as renal infarction and congenital polycystic kidneys.^{6, 10, 17}

CHOICE OF MATERIAL

In the present analysis only the commoner types of chronic renal disease that often terminate in uremia are considered. No analysis has been made of the degenerative renal diseases, such as nephrosis and amyloid disease, of congenital anomalies, of renal tuberculosis or of obstructive lesions without infection.

The cases were originally selected from the autopsy files of the Boston City Hospital and represent consecutive cases of each type, with the exclusion of those in which the pathological diagnosis was not clear, those with some other major disease that might complicate the interpretation of the clinical picture, such as heart disease of other etiology, and those in which there were insufficient clinical data. An exception was made only in cases of decompensated benign nephrosclerosis, for in this group only those patients with benign nephrosclerosis dying in uremia were included, which of course left out the vast majority of patients with essential benign hypertension. The selection and classification were therefore made on the basis of pathological findings.

The clinical studies were such as might be expected to be made routinely on the wards of a large general hospital and varied in extent and probably in accuracy. A few patients were personally observed by us.

CLASSIFICATION

This study has been limited to the three commoner large groups of chronic nephritis, each of which has been subdivided in the following manner:

- I. Glomerulonephritis
 - a. Subacute
 - b. Chronic
- II. Nephrosclerosis
 - a. Benign
 - b. Malignant
- III. Pyelonephritis
 - a. Healed
 - b. Chronic

Although the concept of glomerulonephritis is an old and broadly accepted one, it is probable that many of the lesions that were so diagnosed in the past would now be called some stage of pyelonephritis or malignant nephrosclerosis. The concept of glomerulonephritis should be restricted, in our view, to lesions in which the primary change is a diffuse involvement of the glomeruli by an active or healed inflammatory process. Cases with

a prolonged course can be divided more or less into two stages, usually known as subacute and chronic, although the dividing line is not a sharp one. In Table 1 are given the gross and microscopical criteria used for such separation, as well as the characteristic features of the other renal lesions under discussion.

Nephrosclerosis includes that group of kidneys in which the first and fundamental change is an arteriolar sclerosis. It has been suggested by Arthur Ellis,⁹ who bases his conception on the experimental work of Wilson and Byrom,¹⁸ that these changes are probably the result rather than the cause of an associated hypertension. A similar point of view is taken by Dock,¹⁹ who summarizes the arguments in its favor. There is, however, another school of thought that maintains that renal arteriolar sclerosis is the primary disease, the hypertension resulting from the renal ischemia. This is the belief of Scott,²⁰ and it is at least assumed by Goldblatt, Kahn and Lewis²¹ in a summary of the treatment of experimental hypertension.

As a result of the renal arteriolar lesions, changes are produced in the kidney that may or may not, according to their degree, lead to renal decompensation. Pathologically the distinction between benign and malignant nephrosclerosis is made mainly on the basis of the type of arteriolar sclerosis present. In the benign form this is chiefly hyaline in type, the hyaline thickening of the wall leading to marked narrowing or even complete occlusion of the vessel. In malignant nephrosclerosis the arteriolar sclerosis is hyperplastic in type, the lumens being narrowed or occluded by a proliferation of cells, probably fibroblasts, between the muscularis and the endothelium. Necrosis of the wall with hemorrhage into it, polymorphonuclear infiltration and fibrin deposition (necrotizing arteriolitis) often occur but are not so pathognomonic of the condition as is the hyperplastic change. Other gross and microscopical criteria are given in Table 1.

Not uncommonly borderline cases with combinations of the features of benign and malignant nephrosclerosis are found. Most of these patients are between fifty-five and sixty-five years of age and clinically are usually considered as examples of the malignant form.

Our conception of pyelonephritis is essentially that of Weiss and Parker.⁶ The important gross and histologic characteristics are given in Table 1. The vascular picture is somewhat complicated. As shown by Weiss and Parker, hyperplastic arteriolar sclerosis may be restricted to those areas where the inflammatory process was originally present.

In the cases associated with hypertension, however, arteriolar sclerosis, usually hyperplastic in type, is present not only in the scarred areas but throughout the kidneys and also in other organs of the body. This diffuse process is probably best explained as caused by the hypertension.

The separation of chronic pyelonephritis from healed pyelonephritis is not an easy one, particularly from the purely pathological standpoint. It depends on one's being able to find evidence of active infection still present in the lesions. Such

or significant hypertension exceeded the number with subacute or chronic glomerulonephritis, as has been pointed out by Weiss and Parker.⁶

Essential hypertension, of course, occurs with great frequency, but the number of cases classed as decompensated benign nephrosclerosis is less than the incidence of malignant nephrosclerosis.

Age at Death

It will be seen from Table 2 that subacute and chronic glomerulonephritis, malignant nephro-

TABLE 1. *Gross and Microscopic Characteristics of the Kidneys in Chronic Bright's Disease.*

CHARACTERISTICS	SUBACUTE GLOMERULONEPHRITIS	CHRONIC GLOMERULONEPHRITIS	BENIGN NEPHROSCLEROSIS	MALIGNANT NEPHROSCLEROSIS	HEALED PYELONEPHRITIS	CHRONIC PYELONEPHRITIS
Gross	Large or normal, pale yellow, smooth to granular.	Pale, contracted, granular.	Contracted, granular, prominent blood vessels	Slightly contracted, mottled pale and red, petechial hemorrhages	Coarsely scarred or very contracted and granular	Coarsely scarred or very contracted and granular, abscesses (?).
Microscopic involvement	Diffuse	Diffuse	Focal	Focal	Focal or diffuse	Focal or diffuse
Glomeruli	Fresh crescents, increased cellularity.	Old crescents, adhesions, fibrosis	Normal to fibrosed	Normal, infarcted, necrotic or inflammatory	Reduced in number, pericapsular fibrosis	Reduced in number, pericapsular fibrosis
Tubules	Fatty degeneration	Atrophy and dilatation	Atrophy and dilatation	Hyaline droplets, fatty degeneration	Thyroid like areas	Thyroid like areas, with polymorphonuclear leukocytes in some
Interstitial tissue	Edema; doubly refractile fat.	Fibrosis	Fibrosis	Perivascular lymphocytic infiltration	Fibrosis, lymphocytic infiltration.	Fibrosis polymorphonuclear, lymphocytic and plasma-cell infiltration.
Blood vessels	Hyaline or hyperplastic arteriolar sclerosis	Hyaline or hyperplastic arteriolar sclerosis	Hyaline arteriolar sclerosis, atherosclerosis of arteries.	Hyperplastic arteriolar sclerosis, necrotizing arteriolitis	Hyaline or hyperplastic arteriolar sclerosis	Hyaline or hyperplastic arteriolar sclerosis

evidence usually consists of the presence of leukocytes in the interstitial tissue or in the lumens of the tubules. Sometimes even organisms can be demonstrated.

RESULTS

Relative Incidence

Since the cases studied were a selected group, they are not indicative of the relative incidence of the various types of chronic Bright's disease. Healed pyelonephritis, as judged from the presence of old scarring of the kidney, is of common occurrence. A recent study of Kinney and Mallory,²² as yet unpublished, based on 1000 consecutive post-mortem examinations at the Boston City Hospital, indicates that it may occur in nearly 14 per cent of all persons. Many of these lesions were minor in degree, and in life the patients had few or no clinical manifestations referable to their kidneys. Nevertheless the number of patients who had disease of such degree as to lead to renal failure

sclerosis and healed pyelonephritis in this series are diseases of youth and early middle age.

Predisposing Factors

Infection appears to bear a definite relation to glomerulonephritis. All but 1 of the patients with subacute glomerulonephritis and 6 of those with chronic glomerulonephritis had scarlet fever, sore throat or some other respiratory infection preceding the onset of symptoms. On the other hand, a clear-cut history of acute glomerulonephritis or of acute pyelonephritis was rarely elicited in the patients with chronic glomerulonephritis and with healed or chronic pyelonephritis, respectively. A history of toxemia of pregnancy occurred in only 2 cases, both in the healed pyelonephritis group.

Abnormalities of the urinary tract were not found in any group except that of pyelonephritis. One patient with healed pyelonephritis had a unilateral renal calculus with some hydronephrosis. Of the 6 cases of chronic pyelonephritis 1 patient

showed unilateral renal calculus with hydronephrosis; 1, an infant of eight months, had hydroureters; and 1 had prostatic obstruction.

disease for two and a half, three and six years, respectively. In the other groups the known duration varied from a few months to many years.

Known Duration of Renal Disease and of Hypertension

Terminal Arterial Blood Pressure

The known duration of renal disease and of hypertension as judged from the records is proba-

Figure 1 shows the average range of blood pressure for each patient during his terminal illness. The marked hypertension, especially diastolic, was

bly an inaccurate indication of their actual duration. Nevertheless, it is of interest. In benign nephrosclerosis, known hypertension was frequently diagnosed some years before renal disease, whereas in the other groups renal disease was diagnosed initially or the hypertension and renal disease were first observed at the same time.

The relatively short duration of the known disease in malignant nephrosclerosis is striking, only 1 patient living three years after a diagnosis was first made, and the rest dying within two years. The duration of disease in subacute glomerulonephritis is also usually short (one year or less), although 3 patients were known to have had the

consistently seen in malignant nephrosclerosis and was often but not always encountered in benign nephrosclerosis and chronic glomerulonephritis. In subacute glomerulonephritis and in healed pyelonephritis the ranges of pressure were wide, whereas only 1 case of chronic pyelonephritis exhibited well-marked hypertension.

Retinal Findings

Retinal findings were variously described in the records. An attempt has been made to classify them in a general way according to the terminology of Wagener and Keith.¹⁴ Grade 4 changes consist of papilledema, usually with other severe

manifestations of retinal and vascular changes as well. This so-called "hypertensive neuroretinopathy" is generally agreed to constitute a grave prognostic sign, and by many its presence is considered to merit a diagnosis of malignant hypertension. Although 9 of the 10 cases of malignant nephrosclerosis in which the eyegrounds were ex-

type, since it was absent in 2 cases and of slight degree in several others. Conversely, marked microscopic pyuria may occur in lesions of other types than pyelonephritis.

Too few tests for bacteriuria and pyelographic examinations were made to merit analysis. Such studies might in some cases have been of diagnos-

FIGURE 1. Average Blood-Pressure Readings in Various Types of Chronic Bright's Disease at Time of Last Hospital Entry.

amined showed papilledema, it is of great interest that 7 of 9 cases of healed pyelonephritis had similar fundal changes, and they occurred in one or more cases of each of the other groups. Hence, although the pathologic entity, malignant nephrosclerosis, almost invariably presents the clinical picture of malignant hypertension, the converse is not true. Clinical malignant hypertension, as judged especially by retinal changes, not only is produced by malignant nephrosclerosis, but often occurs in healed pyelonephritis and may be found in any of the types of nephritis discussed here.

Urinary Findings

As shown in Tables 2 and 3, no pattern of urinary findings is pathognomonic of any one type of nephritis. However, marked proteinuria, hematuria, pyuria and cylindruria occurred with great regularity in subacute glomerulonephritis and almost as often in chronic glomerulonephritis. Malignant nephrosclerosis presented a picture ranging from an almost normal urine to one resembling that of glomerulonephritis; the same was true of benign nephrosclerosis, although severe changes were uncommon.

Although pyuria was always present in chronic pyelonephritis, this was not true in the healed

type help, but it should be pointed out that in our experience, as well as that of others, pyelonephritis may exist with normal pyelographic findings and, at least in the healed type, without bacteriuria.

Few patients were followed in this hospital over a long period with careful studies of their urine. However, in those who were so followed it was apparent that in glomerulonephritis gross urinary abnormalities were present early in the course of the disease, often before the development of significant hypertension. The changes persisted, although terminally the albuminuria and abnormalities in the sediment occasionally diminished slightly in amount.

In contrast, patients with nephrosclerosis frequently exhibited comparatively little in the way of urinary abnormalities until late in the disease. The patients with healed pyelonephritis did not follow a consistent pattern. In some of these cases, as in nephrosclerosis, the urine was normal or nearly so for long periods of time, whereas in others persistent or intermittent pyuria occurred and microscopic hematuria was occasionally found.

Leukocyte Count

Leukocytosis of some degree was present in almost all cases at some time.

Nephrotic Stage

By the term "nephrotic stage" is meant the clinical syndrome in which generalized edema, usually

This type of edema is related to hypoproteinemia and marked proteinuria. Consistent with this is the fact that the plasma protein of 7 of 9 patients with subacute glomerulonephritis was below 5 gm. per 100 cc. during the last part of their stay in the hospital, and in no other group were protein levels below 5 gm. found. The patients with subacute glomerulonephritis either showed nephrotic edema at the time of death or had had it in the recent past. Those with chronic glomerulonephritis had exhibited edema months or years prior to death.

In 2 of the cases of subacute glomerulonephritis with nephrotic edema, the edema cleared in the weeks before death as renal failure advanced; in the other 7, however, it persisted. In 3 of these cases mild heart failure occurred in the late stages of the disease.

Edema that was not clearly cardiac occurred in 2 patients with malignant nephrosclerosis and in 1 with healed pyelonephritis, but this edema was mild and may well have been due to other than renal causes.

Renal Failure (Uremia)

If one takes as a rough measure of uremia the presence of a blood nonprotein nitrogen above 60 mg. per 100 cc.,—not due to extrarenal causes,—all the patients in all groups suffered from it during their terminal hospital stays, with the exception of 2 cases of subacute glomerulonephritis and 1 each of malignant nephrosclerosis and healed pyelonephritis (Tables 2 and 4). Even these 4 patients had nonprotein nitrogen levels above 50 mg. at some time during their final stay in the hospital. The degree of nitrogen retention was studied but

marked in degree, dominates the picture. There was no known nephrotic stage in any of the disease groups except those of subacute and chronic

glomerulonephritis. In the subacute group it was present in 9 of 10 cases, lasting from a month to a year. In the chronic group it occurred in only 3 of 10 cases.

showed nothing characteristic in the different groups.

In our series the absolute duration of the renal failure frequently could not be told, since many of

the cases came under observation only at a time when uremia was already present. However, from the known duration of uremia shown in Figure 2 it can be seen that uremia of relatively long duration is common in glomerulonephritis and benign

and 4. It was commonest in patients with decompensated benign nephrosclerosis, where, in spite of the fact that only cases involving death in uremia were chosen, 7 of 11 had significant degrees of heart failure. Moreover, it occurred frequently in

FIGURE 2. Known Duration of Nitrogen Retention (above 60 mg. per 100 cc.) in Various Types of Chronic Bright's Disease.

nephrosclerosis and may occur in pyelonephritis.

Tests designed to show early diminution in renal function, such as concentration tests, phenolsulfonphthalein excretion, clearance tests and so forth, were done too infrequently to be of value in this study.

Anemia

In general the anemia was of a normocytic type and tended to be related to the degree and especially the duration of renal failure. In 2 cases anemia of this type had existed for three months before the nitrogen retention exceeded 60 mg. per 100 cc., and in 2 cases nitrogen retention of this amount or more had persisted for twelve and twenty-four months, respectively, before anemia occurred, but in all other cases the known durations of anemia and of nitrogen retention tended to parallel each other, and in every case in which anemia did not occur the known uremia had existed for six weeks or less.

Heart Failure

The importance of heart failure as a primary or contributing cause of death is shown in Tables 7

chronic glomerulonephritis and malignant nephrosclerosis.

Hypertensive Encephalopathy

Table 2 shows the incidence of this manifestation, which was taken to include episodes of blurred vision, transitory loss of consciousness, aphasia, transient paralysis and so forth. It appeared to be correlated to some extent with the degree of hypertension or of generalized vascular disease or both.

Cerebral Accidents

The occurrence of cerebrovascular accidents is shown in Table 2. In both cases of malignant nephrosclerosis, in 2 cases of healed pyelonephritis and in 1 case of chronic glomerulonephritis the cerebral episodes were the chief immediate cause of death (Table 4).

DISCUSSION

The clinical manifestations in the advanced stages of chronic Bright's disease are not specific for different pathological types. This has been pointed out before by others, but requires re-

emphasis since there still exists confusion in the minds of many. These clinical manifestations are in the main dependent on either failing renal function or arterial hypertension and its sequelae or both. A lesion of any type if sufficiently severe, diffuse and long lasting may so damage the kidney as to cause its function to fail, and when renal failure occurs the clinical picture tends to conform to a certain general pattern regardless of the initiating cause.

Moreover, it is also increasingly evident that many types of renal disease may be accompanied by chronic hypertension, that this hypertension may be of any degree of severity, and that when it is once established the complications that occur are those of chronic hypertension and its associated vascular disease, and are not dependent on the primary causative factor. In certain types of nephritis—for example, glomerulonephritis and pyelonephritis—there is good reason to believe that the renal factor is of primary importance in producing the hypertension. In nephrosclerosis, on the other hand, there is as yet no good evidence that the renal pathologic changes are not secondary to a preceding hypertension of unknown etiology, although once established a vicious circle may be set up, so that the renal ischemia resulting from the nephrosclerosis may aggravate the arterial hypertension, which in turn increases the pathologic change within the kidney.

There are, however, certain features in the life history of the different varieties of chronic nephritis that occur with greater frequency in one type than in another, and there are a few clinical manifestations that are to be found in one type only. Hence the attempt of the clinician to make a diagnosis based on the underlying pathology is not entirely fruitless, since in many cases a proper evaluation of the various clinical factors should lead to the correct diagnosis.

The clinical findings can best be evaluated and understood in the light of the present knowledge of the pathogenesis of the various types of chronic nephritis. Thus, although the fundamental etiology of nephrosclerosis is unknown, it is clear that in the fully developed state there is evidence of widespread vascular disease, and that the malignant type differs from benign nephrosclerosis in the severity of the changes and the rapidity with which they occur. It is obvious, therefore, why nonrenal manifestations, especially in the brain, are commoner in nephrosclerosis, particularly the malignant type, than in the other groups. In malignant nephrosclerosis it is not uncommon for failure of the kidneys, heart and cerebral circula-

tion to occur almost simultaneously. As emphasized by Weiss and Parker,⁶ widespread vascular disease is infrequent in patients with hypertension secondary to pyelonephritis.

Several factors combine to produce strain on the heart in chronic nephritis: the height of the blood pressure; the duration of the hypertension; coronary vascular disease; the anemia, which lowers the oxygen-carrying power of the blood and tends to produce an increased cardiac output; and the toxic effect of the uremia on the myocardium. Hence it is not surprising that heart failure occurs so frequently in all groups.

The renal lesion is most obviously present and dominant in glomerulonephritis, and in this group, findings directly related to renal involvement are most constantly present. A striking finding in our series was that the nephrotic syndrome occurred only in glomerulonephritis.

The only variety of Bright's disease that usually runs a characteristic clinical course easily distinguishable from the other types is subacute glomerulonephritis. The onset can most often be definitely dated following an upper respiratory infection, and may be typical of acute nephritis. Occasionally there is a subsequent interval when the patient is free of symptoms, with one or more relapses following further respiratory infections, but frequently the course is progressive from the onset, with nephrotic edema dominating the picture and death ensuing in a few months to a few years. Increasing impairment of renal function takes place, followed by uremia, sometimes hastened by intercurrent infections. The manifestations and complications of hypertension are ordinarily less striking in this type of nephritis than in the others, although even here some degree of heart failure is not infrequent in the late stages.

Whether it is justified on either clinical or pathological grounds to classify subacute separately from chronic glomerulonephritis is open to question. All gradations between the two types exist. The disease is considered subacute when it has progressed so rapidly that death occurs before scarring, and hypertension with its vascular changes takes place to a significant or dominating degree. Conversely, in chronic glomerulonephritis the initial renal lesion is often not so extensive as to produce the nephrotic syndrome or so overwhelming as to result in early death, but does result in renal changes leading to hypertension. There is thus initiated the vicious circle of hypertension and vascular renal change already mentioned. In any case the term "subacute" is an unfortunate one, since this stage of the disease may last for years.

SUMMARY AND CONCLUSIONS

A clinicopathological study has been made of chronic Bright's disease, comprising (as defined by post mortem examination of the kidneys) 10 cases of subacute glomerulonephritis, 10 of chronic glomerulonephritis, 11 of decompensated benign nephrosclerosis, 11 of malignant nephrosclerosis, 11 of healed pyelonephritis and 6 of chronic pyelonephritis.

Glomerulonephritis, malignant nephrosclerosis and healed pyelonephritis terminated in youth and early middle age, benign nephrosclerosis occurred after fifty, and chronic pyelonephritis was found at all ages.

An acute onset following respiratory infections usually occurred in subacute glomerulonephritis but was recorded much less often in chronic glomerulonephritis. A history of acute pyelitis was rarely elicited in the pyelonephritic cases.

The known duration of disease was usually relatively short in malignant nephrosclerosis (two years or less, with one exception), in the other conditions the range of duration was much greater.

In malignant nephrosclerosis, terminally a well marked arterial hypertension was consistently present, and this also usually occurred in benign nephrosclerosis, healed pyelonephritis and chronic glomerulonephritis.

Nine of 10 cases of malignant nephrosclerosis and 7 of 9 cases of healed pyelonephritis showed reinitis with papilledema. This also occurred in 25 to 50 per cent of the cases in the other groups.

There is no pattern of urinary findings pathognomonic of any one type of nephritis. In healed pyelonephritis the urinary findings may be minimal, and pyuria may be absent.

The nephrotic syndrome occurred only in glomerulonephritis.

Renal failure occurred in all cases, although in 2 cases of subacute glomerulonephritis and 1 each of malignant nephrosclerosis and healed pyelonephritis it was minimal. Uremia of relatively long duration is frequent in glomerulonephritis and benign nephrosclerosis and may occur in pyelonephritis. Anemia tended to be related to the degree and especially the duration of renal failure.

Heart failure occurred commonly in all groups

and with great frequency in both types of nephrosclerosis. It was often the primary or an important contributory cause of death.

Cerebrovascular symptoms were apparently related to the degree of hypertension or of generalised vascular disease or both, and were commonest in malignant nephrosclerosis.

The clinical manifestations in advanced stages of chronic Bright's disease are not specific for different pathological types. They are, in the main, dependent on failing renal function or on arterial hypertension and its sequelae or both. There are, however, certain features in the life history of the different types of Bright's disease that occur with greater frequency in one type than in another, or rarely are seen only in one. Hence, a clinical diagnosis based on the underlying pathology should be attempted and may be helpful in governing prognosis and treatment.

FAMILIAL AURICULAR FIBRILLATION*

LOUIS WOLFF, M.D.†

BOSTON

AURICULAR fibrillation is one of the commonest disorders of the cardiac mechanism, and its frequent occurrence in patients with otherwise normal hearts is now widely recognized. In spite of this, its familial incidence has been observed but rarely. The first recorded observation of this sort was made by Orgain, Wolff and White¹ in 1936. In 1942, Levy² reported the occurrence of paroxysmal auricular fibrillation and flutter without signs of organic cardiac disease in two brothers. The present paper records in detail the findings in three brothers with auricular fibrillation, mentioned briefly in the earlier report,¹ as well as 2 new cases of auricular fibrillation in brothers.

CASE REPORTS

CASE 1. H.K., a 25-year-old real-estate agent, presented himself for examination in 1927 for the purpose of having his heart "straightened out," so that the extra premium he was paying for life insurance might be removed. His mother and father, as well as two brothers (Cases 2 and 3), were alive and well. His mother was said to have had rheumatic fever. There was a possible history of diphtheria in childhood, mild influenza in 1918 and occasional sore throats prior to tonsillectomy in 1921. Frequent nosebleeds had occurred in childhood. Four to five years previously, the patient suffered from back pain, for which no cause could be found.

At birth, the attending physician thought the heart was irregular. From the age of seven through childhood he had always had a grossly irregular pulse. The diagnosis of auricular fibrillation was made for the first time when he was 20 years old, and a course of quinidine therapy at that time failed to abolish the abnormal rhythm. He lived an active, unrestricted life, and had palpitation only when excited. Although he was nervous and had fainted several times, he felt perfectly well and was apparently in excellent health. He smoked twenty cigarettes every day and drank occasionally, sometimes to excess.

Physical examination showed a well-built, healthy-looking young man. The only abnormality was the presence of a grossly irregular heart and a slight, inconstant apical systolic murmur. The apical rate was 80 per minute and was uninfluenced by exercise. The blood pressure was 110/70. The electrocardiogram was normal except for auricular fibrillation. After complete digitalization, quinidine sulfate restored normal rhythm. An electrocardiogram taken within an hour showed a PR interval of 0.16 second and digitalis T waves.

One and a half years later, after a drinking bout, auricular fibrillation recurred. Quinidine alone failed to restore normal rhythm. The patient was therefore digitalized. Quinidine then abolished the abnormal rhythm.

*From the Cardiac Clinic and Electrocardiographic Laboratory, Beth Israel Hospital.

†Instructor, Courses for Graduates, Harvard Medical School; associate visiting physician and chief of Cardiac Clinic, Beth Israel Hospital.

He remained well for 2½ years, when another drinking bout was followed by the occurrence of auricular fibrillation. Again digitalis and quinidine restored the normal cardiac mechanism. Another recurrence of auricular fibrillation, without obvious cause, took place 1½ years later. Although digitalis and quinidine again restored normal rhythm, the rhythm became irregular within 2 months. After a short trial of quinidine therapy by the family physician without success, further treatment was refused. Up to the present time (February, 1943), the patient's health has remained excellent in spite of persistent auricular fibrillation. Digitalis has not been required.

CASE 2. V.K., a 31-year-old businessman, presented himself for examination in March, 1928, for treatment of a cardiac condition that he believed similar to that of his brother (Case 1). He had had measles, diphtheria, pertussis, mumps and tonsillitis in childhood. At the age of 8, he had pains in the legs, but was not disabled. The tonsils and adenoids were removed when he was 13 years old. In 1917, he had influenzal pneumonia and was in bed for 2 weeks. He smoked thirty cigarettes daily, but used very little alcohol, coffee or tea. As far back as he could remember, he had been very nervous and had had a quick temper. During the last 4 years his responsibilities had greatly increased, and he had had several fainting spells during this period.

The heart had been irregular since early childhood, but a diagnosis of auricular fibrillation had been made for the first time 7 months before the present examination. The patient played tennis and baseball and was very active generally. His only complaint was palpitation under great excitement.

Physical examination showed a well-developed, fairly well-nourished man. The heart rhythm was absolutely irregular at a rate of 76 per minute, which corresponded with the pulse rate. The sounds were of good quality and there were no murmurs. The blood pressure was 108/80. Electrocardiographic tracings showed auricular fibrillation with a ventricular rate of 70. There were no other abnormalities. After complete digitalization, quinidine caused a reversion to normal rhythm. Electrocardiograms then showed a PR interval of 0.20 second and digitalis T waves. Examination of the heart revealed no abnormalities except for a systolic murmur that was audible at the apex and pulmonic area but disappeared completely on full inspiration. Two days later the PR interval was 0.16 second.

When the patient was last seen, 20 months after the first examination, normal rhythm was still maintained. He had been living his usual active life, smoking as much as ever and occasionally drinking, without any harmful effects.

CASE 3. M.K., a 24-year-old law student, was first seen in June, 1928, at the request of his two brothers (Cases 1 and 2). During childhood he had had measles, an occasional cold and rarely a sore throat. For several years, when tired, he had had generalized, steady, dull pains in

the legs. At the age of 9, herniotomy and tonsillectomy were performed, and at the age of 15 the appendix was removed. The patient smoked twenty to twenty five cigarettes every day, and drank two or three cups of coffee and one cup of tea daily and alcohol irregularly.

At the age of 14, he was told that his heart was irregular and was advised to avoid strenuous exertion. Nevertheless he played tennis, baseball, football and hockey and could swim 3 miles without untoward symptoms. He had palpitation only when excited. Nervousness was always marked and fainting or dizziness occasionally occurred.

Physical examination revealed a tall, fairly well nourished young man. There were no abnormalities except for an absolutely irregular cardiac rhythm. The apex and pulse rates were 80 per minute. The blood pressure was 118/80. Electrocardiograms were normal except for auricular fibrillation, the ventricular rate was 70. After complete digitalization, quinidine restored normal rhythm. Electrocardiograms taken immediately after the change in rhythm showed a PR interval of 0.20 second and digitalis T waves.

The patient was seen for the last time 2 months after the first examination. Normal rhythm was still maintained.

CASE 4 S O S, a 35 year-old physical director was first seen in April, 1928. The chief complaint was palpitation of 10 years' duration. The past history was negative except for Neisserian infection 17 years previously, mild influenza in 1918 and psoriasis 1 year previously.

His general health had always been excellent except for attacks of palpitation, which occurred about once a week and lasted half an hour and were apparently related to excitement, exertion or the drinking of whiskey. During the attacks, he was conscious of rapid and irregular heart action. Although he felt weak, he continued whatever activity he was engaged in. Less frequent attacks of a different type of palpitation occurred in which the heart beat much more rapidly and was regular except for occasional intermittence. They were stopped by bending forward. The patient's activities consisted of wrestling, boxing, swimming and road work; he could run 10 miles without untoward symptoms. He was nervous and introspective.

Physical examination disclosed a well-developed and well-nourished muscular, healthy athlete. The heart was normal, but the first apical sound was reduplicated. The blood pressure was 104/70. The tip of the spleen was just palpable. Roentgenographic measurements of the heart were within normal limits. The blood Wassermann reaction was negative. Electrocardiograms were obtained during paroxysms of auricular fibrillation as well as during normal rhythm.*

Seven years later (1935), after untreated persistent auricular fibrillation for 6 months, the patient was examined at another clinic,⁴ where congestive failure and moderate cardiac enlargement were found. Following digitalization, quinidine restored normal rhythm. Improvement was striking and for the next 5 years he was able to carry on well. There was an occasional paroxysm of auricular fibrillation. In 1939, the transverse diameter of the heart was 14.8 cm, compared to 14.1 cm in 1928.

CASE 5 S S, the 25 year-old brother of the patient in Case 4 entered the Beth Israel Hospital in March 1931,

complaining of attacks of palpitation of 2 years' duration. In childhood he had had diphtheria, measles, scarlet fever and frequent sore throats. He drank whiskey and beer occasionally and two or three cups of coffee daily, he did not use tobacco.

During the last 2 years he had had several attacks of palpitation lasting as long as 36 hours. Ten months before admission, after exercising in a gymnasium, he had an attack accompanied by constricting precordial pain. Examination showed auricular fibrillation and spontaneous pneumothorax (x-ray). Following this he had palpitation and dyspnea, especially at night, but continued working strenuously as a warehouseman and played basketball and other games. He was nervous and introspective.

Examination revealed no abnormal findings except auricular fibrillation, with an apical rate of 90 per minute. The blood pressure was 122/80. The basal metabolic rate was +10 per cent. Electrocardiograms showed a tendency to right axis deviation, auricular fibrillation with a ventricular rate of 100 and normal T waves and RST segments. After reversion to sinus rhythm, normal P waves and PR intervals were present. A roentgenogram of the chest revealed slight scarring of the left apex and emphysema. After complete digitalization, quinidine restored normal rhythm.

During the succeeding 8 years, paroxysms of auricular fibrillation have recurred occasionally, but the patient's general health has remained good. At present there is no evidence of structural heart disease.⁵

DISCUSSION

The great frequency and ease of recognition of auricular fibrillation warrant the conclusion that the familial occurrence of this arrhythmia is rare. Indeed, the two sets of brothers here reported are unique in medical literature, in the cases reported by Levy,² one brother had auricular fibrillation, the other auricular flutter. This is in marked contrast to other common disorders of the heart such as rheumatic, hypertensive and coronary heart disease, in which it is not unusual for several cases to occur in a single family.

There are several noteworthy features in the first set of brothers (Cases 1, 2 and 3). One of them had frequent nosebleeds, the other two growing pains in childhood. During the fetal life of M K (Case 3), his mother is said to have had rheumatic fever. All three brothers had permanent auricular fibrillation, in contrast to paroxysmal fibrillation in the remaining cases in a series with normal hearts previously reported.¹ An arrhythmia was constantly present years before a diagnosis of auricular fibrillation was made, suggesting that an abnormal mechanism was present at birth or developed early in life. Congenital auricular fibrillation is suggested, particularly in Case 1. The three brothers lived normal, unrestricted lives and two of them engaged in strenuous sports without difficulty of any sort. Although the ar-

*A more complete description of these electrocardiographic tracings may be found in a previous publication by Wolff, Parkman and Willet.²

rhythmia was untreated, the ventricular rates were slow, even after exercise. Auriculoventricular conduction time, measured in each case immediately on resumption of sinus rhythm, was normal. It was thought that an unusually rapid auricular rate (circus movement) might be responsible for the slow ventricular rate, since it was possible to count 800 oscillations to the minute in the limb leads as well as in chest (CB) leads (Case 3). Notching of the auricular deflections, however, could have accounted for the apparently rapid rate. A more likely explanation for the slow ventricular rate was furnished by the evidence of strongly preponderant vagal tone, which also may have been a factor in the production of auricular fibrillation.⁶⁻¹⁰ With normal rhythm, each of the brothers had a very slow and irregular heart (sinus arrhythmia). Nervousness, low blood pressure, dizziness and fainting spells were also present. There was no evidence of thyrotoxicosis.

The benign nature of auricular fibrillation, provided that the ventricular rate is controlled and embolism does not occur, is illustrated by these cases. In spite of the abnormal rhythm of many years' duration, completely unrestricted activity was possible, even without the use of digitalis or other cardiac drugs. The heart size remained normal, and it was impossible to demonstrate any structural abnormality whatsoever.

Case 4 is of historical interest, being the first in which the combination of short PR interval, changes in QRS complexes resembling bundle-branch block and paroxysmal tachycardia was recognized as a distinct clinical entity.³ This mechanism was not demonstrable in the patient's brother (Case 5), but in other respects they were much alike. There was no evidence of thyrotoxicosis.

The value of the combined administration of digitalis and quinidine for abolishing auricular fibrillation, especially when quinidine alone is ineffective, is again demonstrated by these cases.¹¹

SUMMARY

Permanent auricular fibrillation in three brothers and paroxysmal fibrillation in two brothers, with otherwise normal hearts, have been reported. Familial auricular fibrillation is apparently rare, in contrast to certain other cardiac disorders that commonly occur in several members of a single family.

There is evidence of increased vagal tone in these cases, suggesting a probable etiologic factor in the production of auricular fibrillation in certain cases.

Auricular fibrillation, even when untreated and of many years' duration, is entirely benign, provided that the ventricular rate is slow and embolism does not occur. Under these conditions, auricular fibrillation does not cause cardiac enlargement.

The combined administration of digitalis and quinidine for abolishing auricular fibrillation was in these cases superior to the use of quinidine alone.

ACUTE PNEUMONITIS AND PERICARDITIS*

Report of a Case

COMMANDER CLARENCE C. FULLER (MC), U.S.N.R. AND
LIEUTENANT J. WILLIAM QUINLAN (MC), U.S.N.R.

NEWPORT, RHODE ISLAND

BECAUSE of the widespread interest in the prevalent pulmonary infection known variously as pneumonitis, virus pneumonia or simply atypical pneumonia, the following clinical history is presented. We were particularly interested in interpreting the bizarre changes in the electrocardiograms of this patient as correlated with the clinical and x-ray findings. We have subsequently observed the same cardiographic changes, to a lesser degree, in certain other patients suffering from this condition, particularly since we now take routine tracings on all patients with respiratory infections who have temperatures of 100°F or over. In 11 out of 100 cases observed, an elevation of the ST segment of 2 mm above the isoelectric line (generally in Lead 4) was noted. In 5 additional cases there was inversion of the T wave in Lead 4. On recovery, all the variations returned to normal.

CASE REPORT

C J, a 36-year-old man, was admitted to the Medical Service of the United States Naval Hospital at Newport, Rhode Island, on July 8, 1942, complaining of pain in the interscapular region of 1 week's duration and of non-productive cough. The backache was sharp in character and grew worse on movement, breathing or coughing. There had been no chills. He had suffered from an upper respiratory infection (sore throat, fever and cough) 3 weeks previously. This had cleared except for a residual cough.

The past history revealed the occurrence of pleurisy at the age of 11. The family history was noncontributory.

Physical examination disclosed an acutely ill man, slightly cyanotic and somewhat dyspneic. Dullness was noted over the lower lobe of the right lung posteriorly, below the angle of the scapula. Slightly increased breath and voice sounds and coarse rales were heard. The left lung showed dullness at the base, with scattered rales. Percussion of the heart revealed possible enlargement. No murmurs or friction rub was heard. The blood pressure was 110/60. The temperature was 99.4°F, and the pulse 83.

The white cell count was 10,500, with 68 per cent neutrophils and 23 per cent lymphocytes. The sedimentation rate was increased. The antistreptolysin titer was not

mal. The sputum contained some gram positive diplococci, which could not be typed.

X-ray examination revealed an infiltration of both lower lung fields, especially the left, and enlargement of the

FIGURE 1 Electrocardiogram Taken on July 8

cardiac silhouette. An electrocardiogram presented an inverted T wave in Lead 1 and an elevated ST segment in Leads 2, 3 and 4 (Fig 1). On July 11, x-ray films showed recession of the process in the lower left chest but increased density in the lower part of the right lower lobe. On July 15, the T waves were inverted in Leads 1, 2 and 4, with coving (Fig 2), and x-ray examination showed clearing in the right lower lobe but involvement of the right middle lobe. On July 20 (about the 20th day after onset), the T waves were upright in all leads and the electrocardiogram had returned to normal (Fig 3).

The following day, the patient suffered a recurrence of pain between the shoulderblades and in the epigastrium. X-ray examination demonstrated an infiltrating lesion in the upper portion of the right lower lobe. The cardiac silhouette, however, had returned to normal size. An electrocardiogram on the following day revealed inverted T waves in Leads 1, 2 and 3 (Fig 4). The next x-ray examination, performed on July 28, again showed clearing in the right lower lobe but also demonstrated a new le

*This article has been released for publication by the Bureau of Public Relations of the Bureau of Medicine and Surgery of the United States Navy. The opinions and assertions contained herein are the private ones of the writers and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

sion in the right middle lobe. Clinical findings, x-ray evidence and electrocardiographic changes remained the same until August 4, when the chest film showed considerable improvement. The T waves were still inverted in Leads 1 and 3, but by August 12 the tracing had returned to normal and remained so. On that date x-ray examination also showed complete resolution of the pneumonic processes. Sulfonamide therapy was of no avail during either the initial stage of the illness or the relapse.

At the time of first examination the problem appeared to lie in ruling out myocardial infarction. We finally decided for the reasons given below that not coronary occlusion but pericarditis was producing the alterations in the electrocar-

FIGURE 2. *Electrocardiogram Taken on July 15.*

diographic pattern. Early in the differential study dissecting aneurysm was considered, because of the location of the pain, but this possibility was dismissed for want of evidence and because of the manifestations of pulmonary and cardiac changes. Acute mediastinitis was discussed, but Commander E. F. Merrill, roentgenologist at the hospital, did not think that the x-ray evidence supported this possibility. Fiedler's interstitial myocarditis was given but slight consideration. Although this condition may produce somewhat similar electrocardiographic changes and initially may resemble the clinical picture as presented, the return of the heart to normal size and the complete recovery of the patient eliminated this possibility.

The next problem was concerned with the pulmonary changes. It was thought that the rapid-

FIGURE 3. *Electrocardiogram Taken on July 20.*

ity of clearing of the pulmonary fields and the lack of residual alterations eliminated multiple pulmonary infarctions as the source of the lesions. Rheu-

FIGURE 4. *Electrocardiogram Taken on July 22.*

matic fever with rheumatic pulmonary changes and pericarditis might produce the picture de-

scribed. However, at no time did the patient manifest joint involvement and he never exhibited any signs of congestive failure, a finding that is frequently observed with so-called "rheumatic pneumonitis." It is true that the sedimentation rate was increased, but this would be expected in the presence of any acute pulmonary infection. The antistreptolysin titer was normal, however, and we have found this to be uniformly elevated during active rheumatic fever, especially during the first attack. Following the subsidence of the pericarditis no other evidence of acute rheumatic fever with rheumatic heart disease was found. On the basis of these facts we eliminated this entity in favor of one that consistently manifested x-ray changes similar to those described in this case. In addition, subsequent study produced similar though less marked cardiographic changes in about 15 per cent of the patients with these x-ray changes.

DISCUSSION

This patient displayed five distinct areas of pneumonia during the course of his illness, and it will be noted on following the clinical progress that the variations from and return to normal in the electrocardiograms corresponded closely to the pulmonary changes. These variations consisted in elevation of the ST segment and T wave inversion, frequently with coving. The alterations were in the same direction with regard to the base line in various leads in contrast to the changes in myocardial infarction, which are reciprocal, that is, in infarction due to acute anterior coronary occlusion the ST segments may be elevated in Leads 1, 2 and 4 but are depressed in Lead 3. In addition, no Q wave was noted and there was no disappearance of the R wave in Lead 4, as in anterior infarction. In posterior infarction the ST segment is elevated in Leads 2 and 3 but not in Lead 1, where a depression of this segment may be found. The absence of a prominent Q wave in Leads 2 and 3 also helped to differentiate this condition and posterior infarction. Finally, the pattern changed too rapidly and returned to normal too quickly to correspond with that due to infarction.

The changes were in accord with those found in acute pericarditis. They have been described by many investigators and are believed to be due, not to tamponade of the heart, but to acute subepicardial myocarditis. They are characteristically evanescent and may last only a few days, since the

changes are not due to the death of the myocardial tissue but to inflammation. It should be stressed at this point that at no time were any physical signs of pericarditis evidenced—a strong recommendation for the use of the electrocardiogram in similar respiratory infections. The literature shows that the use of Lead 4R is preferable to that of Lead 4F when this condition is suspected, although we used Lead 4F in this study.

One other state should be mentioned as a possible causative factor in the production of the abnormalities, particularly the less marked ones, observed in the tracings of our series. This is hyperventilation, which is known to produce transient electrocardiographic changes. We do not believe that the marked changes produced in the case reported can be accounted for by this phenomenon, but have not investigated it in the other cases with minor changes.

There are three electrocardiographic patterns to be kept in mind as being important from the point of view of differential diagnosis. First of all, a patient who has had a previous pattern of myocardial strain with a superimposed coronary thrombosis may show bizarre tracings similar to those described in this case. Secondly, one must take care to exclude an infarct complicated by bundle branch block. Thirdly, one must rule out a combined anterior and posterior infarction. The absence of a Q pattern aids in this regard, and in addition the study of serial tracings for evidence of a changing pattern as well as observation of the time interval before the pattern returns to normal, is all important.

SUMMARY AND CONCLUSIONS

A case of acute pneumonitis with bizarre electrocardiographic findings, presumably due to acute pericarditis, is reported.

It seems advisable to take electrocardiograms in severe cases of acute atypical pulmonary infection. In this way, acute pericarditis may be diagnosed in the absence of physical signs or before the latter appear, and the tracing may aid in accounting for prolongation of illness or unexplained symptoms and signs. Secondly, one should beware of diagnosing coronary occlusion too readily. Serial tracings should be made, and alterations in pattern should be observed, as well as the time interval, before the return to normal occurs.

MEDICAL PROGRESS

BRIGHT'S DISEASES (Concluded)*

STANLEY E. BRADLEY, M.D.†

BOSTON

Intercapillary Glomerulosclerosis

THE description by Kimmelstiel and Wilson⁵¹ in 1936 of a severe nephrotic syndrome associated with hypertension and uremia, complicating the course of diabetes mellitus and apparently attributable to a sclerotic lesion between the capillaries of the glomerular tuft that they called "intercapillary glomerulosclerosis," has resulted in a reconsideration of pathologic material in many laboratories and in the clinical segregation of such cases in many diabetic clinics where previously they had been overlooked. This movement has continued during the past year with the appearance of case reports and reviews of necropsy material. Horn and Smetana⁵² at Columbia University re-examined diabetic and arterial nephrosclerotic autopsy material and found typical lesions of intercapillary glomerulosclerosis in 22.9 per cent of the diabetic and 25.4 per cent of the nephrosclerotic kidneys, figures that are in striking contrast to those of Siegal and Allen⁵³ of 33.3 per cent and 1.0 per cent, respectively. The lesions were always associated with arteriosclerosis, and it is noteworthy that the severer lesions were always associated with diabetes mellitus. Bell⁵⁴ in Minneapolis has reviewed the kidneys of 460 persons with diabetes, finding hypertension more frequent among them than in the population at large, and finding intercapillary glomerulosclerosis in 20.5 per cent of the diabetic patients. Hyaline masses between the glomerular capillaries, apparently attributable to splitting and thickening of the basement membrane, along with hyalinization of the afferent and efferent arterioles, were the outstanding pathological findings. Horn and Smetana, as well as Bell, stress the nonspecificity of the lesions, which apparently cannot be made the basis of a pathological diagnosis of diabetes mellitus.

Amyloid Nephrosis

During recent years Hass⁵⁵⁻⁵⁷ at Cornell has conducted a study of the nature of the substance deposited throughout the body in amyloid dis-

ease. He has succeeded in separating two protein fractions and a sulfate-bearing polysaccharide from amyloid found in the liver, spleen and other organs. Amyloid from all these sites has common chemical and tinctorial features, although three distinct types of amyloid are identifiable. All are protein-protein complexes and Hass subscribes to the view that all are derived from the deposit and alteration of antibody-antigen combinations. This view is widely held because amyloid deposits appear almost always in conditions where the immune mechanisms have been exposed to prolonged stimulation, as in chronic pyogenic or tuberculous infections. They are easily produced in animals by pyogenic sepsis, especially on the basis of invasion by staphylococci, and by toxins, especially diphtheria toxin when used for the production of immune serum. The appearance of amyloid in such conditions as chronic diffuse glomerulonephritis and multiple myeloma seems to weaken this explanation, but in the first, long-standing occult infections may be at fault, and in the latter the hyperglobulinemia may indicate some connection with the immune mechanisms. The polysaccharide recently isolated by Hass cannot be distinguished chemically from chondroitin-sulfuric acid found in cartilage or from heparin. This gross chemical resemblance to heparin is of interest from the standpoint of pathology, for the lesions are almost invariably found beneath the endothelium of vessel walls. The fact that in vitro production of amyloid with antigen and antibody is not possible is no deterrent to acceptance of the theory, for, as Hass has pointed out, the formation of amyloid is slow and time consuming. Since Congo red, not a unique substance, can easily change the character of amyloid, Hass concludes that many other substances with similar properties are present in the blood and alter the antigen-antibody complex in vivo in a manner that cannot be duplicated in vitro. However, this explanation fails to throw light on the mechanism of the ready and rapid removal of the substance following elimination of the causative focus of infection in many cases. In addition, Snapper⁵⁸ notes the extremely low incidence of amyloidosis in China, where 1.3 per cent of the cases of chronic

The articles in the medical progress series of 1941 have been published in book form (*Medical Progress Annual*, Volume III, 678 pp. Springfield, Illinois: Charles C Thomas, 1942. \$5 00).

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor in medicine, Boston University School of Medicine.

tuberculosis are complicated by the disorder in contrast to varying estimates of 22 to 25 per cent in this country.^{58, 59} Snapper stresses the apparent importance of a milk-free and casein-free diet in determining the low incidence of amyloid disease in northern China.

Considerable interest has been shown during the past year in the refinement and quantitation of the Congo red test. Harmon and Kernwein⁶⁰ suggest the use of 4 mg. per kilogram of body weight, taking blood samples at the usual four-minute and sixty-minute intervals after injection, but Taran and Eckstein,⁵⁹ at the Sea View Hospital, Staten Island, New York, point out that Congo red may be removed so rapidly following administration that a sample taken four minutes later will give a falsely low standard, and they suggest shortening this interval to two minutes.

Benign Proteinuria

The appearance of protein in the urine is usually evidence of an underlying renal disorder of a serious character and may include any of the Bright's diseases. However, cases of proteinuria in the absence of demonstrable renal disease include benign albuminuria, orthostatic albuminuria and the larval nephroses, and may be considered arbitrarily as nephroses. The importance of orthostatic albuminuria today in its relation to military medicine has recently been emphasized by Young and his associates,⁶¹ who report 4 cases of men rejected for military service by medical examining boards because of persistent albuminuria. Extensive studies revealed no renal disease, and it was found that the albuminuria appeared only in the erect posture. These men were then accepted for service. Young emphasizes the benignity of the condition and reviews the cases seen at the Johns Hopkins Hospital. In 67 cases, 4 (6 per cent) proved on follow-up to have chronic nephritis. This incidence, however, is high enough to warrant close follow-ups in all cases and should indicate a somewhat less optimistic outlook, although, of course, coincidence cannot be ruled out as a factor in this small series.

Transient proteinuria (larval nephrosis) frequently appears in the course of acute infectious diseases and febrile states. The usual pathological findings include cloudy swelling of the tubular cells and hyaline-droplet degeneration. Kannerstein⁶² reviewed the renal lesions found at death in the midst of various acute infectious diseases and found tubular changes most marked in diphtheria, where epithelial necrosis appeared in 16 per cent of cases. Interstitial infiltration appeared in 48 per cent of cases of diphtheria and in 77 per cent

of cases of scarlet fever, representing an inflammatory reaction or nephritis that would have been impossible to diagnose clinically.

Therapy of Nephrotic Edema

In most of the nephroses mentioned thus far the management of edema is the outstanding therapeutic problem. Rational therapy must be directed at replacing the lost intravascular protein or at furnishing a substitute with similar properties in order to re-establish normal osmotic relations. To this end, extensive therapeutic programs with the use of transfusions of plasma and serum or concentrates of plasma and serum have been conducted. In many respects this approach has proved disappointing, as is exemplified by the studies in England of Brown, Gray and Mollison⁶³ appearing during the past year. These workers found that concentrated serum and plasma transfusions were not followed in most cases by increased plasma protein and in fact seemed as likely to be followed by adverse effects as by good effects, results confirming several earlier studies in this country. The use of acacia as a substitute for the lost plasma proteins has found support in the United States, particularly at the Mayo Clinic, where acacia has been given an extensive therapeutic trial. During the past year Lehnhoff and Binger⁶⁴ have added 12 more cases of nephrosis treated effectively with acacia to the series already reported from the Mayo Clinic. They find the substance efficacious in relieving the edema of nephrosis and believe that it is safe. However, there is experimental proof that acacia is stored in the liver, to remain there for long periods of time.⁶⁵ Heckel, Erickson, Yuile and Knutti⁶⁶ showed a reduction in plasma proteins after administration of acacia that could not be entirely accounted for by the increase in plasma volume, apparently indicating liver damage with impaired hepatic regeneration of protein. Farr⁴⁹ thinks that the use of acacia is not justifiable since other substances (concentrated human plasma and serum) are available that behave in exactly the same manner and are not dangerous. Obviously, every effort must be made to build up the plasma protein by increasing protein intake. In addition, of course, sodium deprivation is mandatory in preventing to some extent further accumulation of edema fluid.

The diuretics seem to be useful in controlling the edema in many nephrotic patients. Ammonium chloride and the potassium salts are in wide use. Farr⁴⁹ recommends urea in doses of 45 to 60 gm. daily because it is effective and seems to be harmless. The mercurial diuretics have not been proved detrimental to the kidney and are

very effective in establishing diuresis. However, the dangers of their use have received much attention during the past year, and editorial warnings have been sounded in the *Journal of the American Medical Association*⁶⁷ and in the *Lancet*.⁶⁸ These warnings have been addressed to the profession because of the appearance of case reports of sudden death following the administration of mercurial diuretics. DeGraff and Nadler⁶⁹ point out that the usual type of toxic response is attributable to the dehydrating action with chloride loss, resulting in a shock-like state. However, by far the most dangerous type is apparently attributable to ventricular fibrillation due to the direct action of mercury on the heart. In all, some 26 fatal cases have been reported, a number that is infinitesimal in comparison with the millions of injections that have been given.

Mercurial Nephroses

Mercury produces a specific lesion in the renal tubules characterized by necrobiosis, necrosis with sloughing of the epithelial cells into the lumen of the tubule, collapse and rupture of the tubules, and frequently calcification of the necrotic lesions. The lesion is typical in many respects of those seen in the second group of nephroses described above, the necrotizing nephroses. Mercury appears to exert its main effect on the midportion of the proximal tubular segment, rarely with injury to portions of the distal segment and thin segment.⁷⁰ The finding of Holman and Donnelly⁷¹ that hypoproteinemia appears to protect the kidney in dogs may explain the infrequent occurrence of renal damage in nephrotic patients treated extensively with mercurial diuretics.

Sulfonamide Nephrosis

Like mercury, the sulfonamides have proved dangerously nephrotoxic. Numerous reports of cases of renal damage during the course of sulfonamide therapy have continued to appear in the literature during the past year. The renal damage has been attributed to the blocking effect of crystals of the free and acetylated drug. This explanation has much to recommend it in the majority of reported cases, for dilatation of the tubules and the malpighian corpuscles anterior to the blocking crystals is frequently seen. In addition, tubular necroses are often observed, and lesions similar to those seen in the crush syndrome have been reported on several occasions. In these cases a hemolytic anemia due to the drug appears to be the most important underlying factor.⁷² It is worth remarking that these drugs are relatively safe in the presence of uremia resulting from in-

trinsic renal disease. Fishberg,⁷³ for example, describes the successful use of sulfonamide in the treatment of lobar pneumonia appearing in the course of chronic pyelonephritis associated with renal insufficiency and azotemia. This may be ascribed to the low specific gravity of the urine and to the fact that the kidney does not concentrate the drug within the tubular urine at dangerous levels. Small doses of the drug, however, are required to maintain high blood levels in these patients. It is interesting that the sulfonamides appear to become more soluble as urinary concentration increases, owing to the fact that high concentrations of urea render the drugs more soluble.⁷⁴ This finding may have therapeutic bearing in supporting the use of urea during the administration of the drug for its action of inducing diuresis and increasing sulfonamide solubility, as well as for whatever bacteriostatic effect it may have. It cannot be emphasized too frequently that adequate hydration and alkalization are of paramount importance in preventing renal damage by the sulfonamides.

The Crush Syndrome and Related Conditions

During the past year the so-called "crush syndrome" has continued to excite considerable interest⁷⁵ and has stimulated numerous efforts to solve its etiology and pathologic physiology. It is becoming increasingly apparent that an important group of renal disorders, nephrotic in type, is achieving homogeneity as a result of these studies. These nephroses include the renal lesions seen following intravascular hemolysis during malaria (blackwater fever) or after the administration of incompatible blood and those seen during myohemoglobinemia and hemolytic anemia due to sulfonamide, as well as those of the crush syndrome. In all these conditions there are numerous casts in the urine, the collecting ducts and the distal tubules, along with necrotic changes in the tubular cells. In all of them the *sine qua non* in the cycle of events leading to uremia seems to be the extracellular appearance of hemoglobin or other heme-bearing pigment in the circulating blood.

Bywaters and his colleagues⁷⁶⁻⁷⁸ have reported cases of renal insufficiency following crushing injuries seen during the heavy bombing of London in the fall of 1940 as examples of a new syndrome, for they were unaware of similar cases reported in the German literature following World War I. These patients had usually been pinned by the extremities beneath heavy beams or other debris for several hours. Following release they usually

appeared well save for complaints referable to fractures, lacerations and other injuries. The compressed limb was pale, cold and pulseless, with evidence of some motor and sensory loss. Following rescue, tense swelling of the limb appeared and shock became evident with pallor, sweating, hemoconcentration and finally marked hypotension. (Duncan and Blalock⁷⁰ have shown experimentally that the shock is attributable to plasma loss into the tissue at the site of compression where capillary walls are damaged.) The swelling of the limb continued, but shock responded well in most cases to the intravenous administration of fluids and blood. Following recovery from shock the patients seemed well, but the urine was found to appear bloody, to contain albumin, creatine and pigmented granular casts, and to be highly acid. During the next few days the urinary output was as a rule very scanty, but the pigment usually disappeared after the second day. Despite the oliguria, the urine remained dilute. Often the condition of the limb aroused concern, and occasionally amputation in the presence of gangrene was performed. During the first week the blood pressure gradually rose to hypertensive levels, vomiting became a prominent feature, and the blood urea, phosphate and potassium levels gradually rose whereas the carbon dioxide combining power fell. At about the end of the first week, a critical diuresis followed by complete recovery occurred or, more frequently, urine flow ceased altogether and the patient died suddenly after two or three more days in uremia. At autopsy the kidneys were found to be engorged and swollen, with striking changes in the distal segment of the renal tubules ranging from cloudy degeneration to frank necrosis. The distal tubules and collecting ducts were jammed with brown granular casts, which were occasionally extruded into the interstitial tissue through the necrotic tubular wall. The muscular tissue at the site of injury was usually also necrotic and markedly pale. Bywaters⁸⁰ has emphasized the importance of the condition in modern warfare, since the bombing of urban centers is peculiarly adapted to the production of crushing injuries caused by the collapse of shelters, dwellings or other heavy construction. In an air raid as many as 5 per cent of the casualties may be of this type. More than 70 cases had been reported to the Medical Research Council in England by December, 1942.

When first observed, these cases were thought to be examples of transfusion reactions, but it soon became apparent that the syndrome was seen when transfusions had not been administered and

that it appeared only in patients with a history of compression injury. However, Bywaters and his colleagues⁸¹ were struck by the evidence of muscular damage,—namely, the muscular pallor and the creatinuria,—and they believed that a toxic substance, probably myohemoglobin, was released from the muscle. This hypothesis found support in the identification of the pigment in the urine.⁸² Bywaters⁸⁰ next attempted the experimental production of the renal lesion, and claimed success in producing it in the acidotic rabbit following the intravenous injection of myohemoglobin. However, Bing⁸³ was unable to confirm Bywaters's results, since in his experiments myohemoglobin proved harmless in the acidified dog. He suggested that Bywaters's effects might be attributable to the use of foreign protein, since the myohemoglobin used by Bywaters was obtained from some species other than the rabbit, which has no myohemoglobin in its muscular tissue.

Myohemoglobinuria occurs in man, however, under other circumstances, and there it is associated with renal insufficiency, a fact further bolstering Bywaters's hypothesis. Bywaters and Dible⁸⁴ have reported during recent months the eighth case of paroxysmal myohemoglobinuria to have appeared in man. This condition is seen as a rule in horses, where it is a serious complication of sudden exercise after rest or after heavy feeding and is apparently due to muscular loss of myohemoglobin. The affected muscles become stiff and paralyzed, and death occurs in uremia, in 20 to 70 per cent of cases with evidence of sepsis at the end of the first week. Lesions in the kidney resemble those of the crush syndrome.

On the other hand, renal disorders are known that resemble the crush syndrome in every respect but that do not require myohemoglobinemia for their genesis. The so-called "transfusion kidney" and the renal lesions in blackwater fever are striking examples. In such cases, too, a heme-bearing pigment, hemoglobin, is freed in the blood, and renal insufficiency is usually attributed to blockage of the tubules by the casts owing to the relative insolubility of hemoglobin in an acid urine. Since blocking of this sort is seen in the kidney of the crush syndrome and in myohemoglobinuria, a similar explanation has been evoked to account for the failure of kidney function in these disorders. In this view, the released pigment—whether hemoglobin or myohemoglobin—passes through the glomerular membrane and under conditions of acidosis is precipitated in the tubular urine, to form casts that block the further secretion of urine. A number of cogent arguments against

this hypothesis have, however, appeared during the past year. Ayer and Gauld⁸⁵ have pointed out that an identical pathologic picture is seen in the kidneys of severely jaundiced infants with congenital atresia of the bile duct in the absence of any sign of renal insufficiency. In addition, the blockage hypothesis implies some dilatation of the tubules and glomeruli proximal to the point of block, as is seen in obstruction by crystals of the sulfonamides. This is never seen in the renal lesion of the crush syndrome and of the transfusion reaction.⁷² Bywaters⁸⁰ has noted that the scant urine was dilute in all his cases, contrary to one's expectation if mechanical obstruction were to account for the oliguria. Thus it seems that the idea of cast obstruction as the primary cause for the oliguria and renal failure in these conditions must be doubted. In fact, cast formation may be regarded as a phenomenon secondary to a markedly reduced glomerular filtration rate.^{72, 83}

Whatever the mechanism by which renal failure is brought about, it seems likely that it is common to all these nephroses and that a substance toxic to tubular cells and interfering with renal hemodynamics is involved. It also seems clear that this hypothetical substance is derived from or through the agency of the heme-bearing pigment, for the pathologic picture is always seen when a heme-bearing pigment is at large in the blood and may be seen—in transfusion reactions, for example—in cases in which no tissue damage is apparent as a source of a toxic agent. Curiously enough, the heme-bearing pigments do not seem to be nephrotoxic in normal animals and in man. However, renal tubular lesions have followed the intravenous injection of heterologous myohemoglobin in the acidified rabbit⁸⁰ and of homologous methemoglobin in the acidified dog.⁸³ Ferrihemic acid, a breakdown product derived from methemoglobin, has also been used successfully to produce tubular damage in the dog.⁸⁶ Anderson, Morrison and Williams,^{80, 87} who claim that this substance, derived from the pigment of the malarial parasites, is responsible for the kidney lesion of blackwater fever, have expressed the opinion that it acts indirectly through vascular injury and thrombosis rather than directly on the tubular cells. There is much evidence, however, that the tubular cells are directly affected in all these nephroses. Anatomically, there is marked disorganization of the structure of these cells, especially those of the distal segment, and physiologically certain tubular functions, largely carried out in the distal segment, are gravely disturbed. It is noteworthy that acidemia, a prominent clinical feature, is necessary before the lesions can

be produced experimentally. In addition, the urine remains highly acid, despite efforts to alkalinize it, both in man and experimental animals, once the condition has been established.⁷² These facts suggest that the distal segment function of acidification may be involved in some fashion in the initiation and perpetuation of the renal lesion. The ability of the kidney to concentrate the glomerular filtrate, another distal segment activity, is also seriously interfered with, for the urine remains dilute despite the oliguria. Furthermore, there is evidence that the glomerular filtration rate and the renal blood flow are markedly reduced.^{72, 83}

Therapy in these disorders remains largely empirical. Since the scanty flow of urine has heretofore been attributed to blockage by casts of precipitated pigment, it has seemed reasonable to increase water intake as a measure directed to washing out the casts and to alkalinize the urine in order to increase their solubility. In the light of the more recent work, the rationale of this therapy appears to be seriously weakened. It has, however, proved effective in practice, and until better methods based on more complete knowledge are developed, alkalinization and hydration will doubtless remain the procedures of choice. Bywaters⁸⁰ has emphasized the value of forcing fluids and of alkalinization in preventing renal insufficiency following compression injuries, and Smith and Evans⁸⁸ give enthusiastic support to these measures in blackwater fever. It is conceivable that hydration is of value because it may increase the decreased filtration rate, but no good evidence that alkaline therapy is beneficial has been adduced. Indeed, it is possible that alkalinization may be harmful,⁷² although this point is highly controversial and awaits further experimental elucidation. Duncan and Blalock⁷⁹ have shown the efficacy of pressure in preventing local loss of fluid following crush injury, and this principle has found clinical application in the hands of Patey and Robertson,⁸⁹ who advocate elastic bandaging of the crushed extremity to prevent shock and the rapid return of toxic substances to the general circuit.

Bilateral Cortical Necrosis

In 1941, Duff and More⁹⁰ reviewed 71 cases of bilateral cortical necrosis reported in the literature and surveyed the experimental work on this subject. The disorder had been observed in 48 pregnant women and in 8 nonpregnant women and in 15 males from thirteen to sixty-four years of age. The necrotic lesions in the renal cortex had appeared in varying degree after a variety

of conditions. There seems to be common agreement that a toxic factor is to blame, and Duff and More believe that the actual effects in the vessels of the renal cortex vary with the degree of hypersensitivity of the vessels and with the intensity and duration of action of the toxic factor, stasis, thrombosis and marked vasoconstriction of the arteries of the renal cortex all playing more or less important roles. In the past year Sheldon and Hertig,⁶¹ at the Boston Lying-in Hospital, have reported 2 cases that are typical in most respects of the clinical and pathologic picture. In each the disorder was observed following abruptio placentae and was characterized clinically by oliguria and anuria, with rapid progression to a fatal termination in uremia. The kidneys were increased in size, with multiple areas of necrosis in the cortical zone. The fundamental lesion consisted of degeneration in the wall of the afferent arteriole at the point of entry into the glomerular tuft, as sorbed with local thrombosis and retrograde extension, resulting in multiple local infarction. Areas of necrosis were also found in other organs, and Sheldon and Hertig were impressed by the appearance of necrotic lesions in the anterior lobe of the pituitary gland in their cases, a finding that led them to believe that the condition was associated in some obscure manner with the endocrinal reorganization in pregnancy. Similar lesions have been produced experimentally in animals by many different methods, and in the past year Christensen⁶² has found that cortical necrosis appears in white rats fed low choline or choline-deficient diets.

The specific toxemia of pregnancy is usually considered to be a nephrosis complicated by hypertension that appears in the course of pregnancy, possibly on a congenital hypertensive background. Advances in this field have recently been discussed by Reid⁶³ in this series of medical progress reports and will not be further considered here.

CASE 29351

PRESENTATION OF CASE

First admission. A forty-two-year-old American salesman entered the hospital because of shortness of breath of one year's duration.

Twenty-one years before admission the patient had an attack of red, swollen joints that lasted five or six weeks and was followed by three months of semi-invalidism. He was well except for occasional stiffness of the joints until eleven years before admission, when he had another similar attack of rheumatism. Several teeth were removed following the attack, and he had had no joint troubles since then. One year before admission he first noted that he became short of breath easily and sweated profusely on the slightest exertion. This condition slowly increased in severity. Two months before entry he had several attacks of acute shortness of breath and consulted a physician, who prescribed digitalis (1 pill three times a day). About then he noticed swelling of the feet and ankles each morning. He continued to work until two weeks before admission, when he consulted another physician, who put him to bed.

Except for the attacks of rheumatism, his past history was negative. One sister died of heart trouble at the age of fifty-eight. His wife had had four pregnancies: the second ended in a miscarriage, in the third, premature twins died shortly after birth, and the other two children were living and well.

Physical examination showed a well-developed and well-nourished man with slight orthopnea but without cyanosis or dyspnea. There was slight engorgement of the neck veins. There were numerous moist rales and dullness at each base. The heart was greatly enlarged to the left, with a diffuse apical impulse at the fifth interspace, 14 cm. from the midsternal line. The right border was 3 cm. from the midsternal line. The rate was regular, and the sounds of poor quality, with a short, high-pitched systolic murmur at the apex. No diastolic murmur or thrill was heard. The

liver was felt 3 to 4 cm. below the costal margin. The spleen was not felt. There was slight pitting edema of the ankles.

The blood pressure was 160 systolic, 110 diastolic. The temperature was 98.6°F., the pulse 80, and the respirations 21.

Examination of the blood revealed a red-cell count of 5,000,000, with a hemoglobin of 75 per cent, and a white-cell count of 11,300, with 61 per cent neutrophils. The urine was negative. A blood Hinton test was negative. An electrocardiogram showed normal rhythm, at a rate of 90, with left bundle-branch block and prominent T waves. A chest roentgenogram showed that the heart lay horizontally in the chest and was greatly enlarged, the enlargement chiefly involving the left ventricle. The pulmonary conus was prominent. The outline of the heart was indistinct because of a rather hazy type of dullness that involved the greater portion of the lungs and was most marked at the right base. The diaphragm was indistinct but appeared to be in the usual position and to move fairly well with respiration. The transverse diameter of the chest was 27.6 cm., and that of the heart 18.9 cm.—6.1 to the right and 12.8 to the left.

The patient improved a great deal on rest, digitalis and ten daily injections of 50 per cent glucose, and was discharged after a period of two weeks. The haziness in both lung fields had definitely cleared.

Second admission (two and a half years later). The patient improved for a short time after discharge but then began to have spells of nocturnal dyspnea and slight orthopnea. The dyspnea increased and the edema became progressively worse so that he was confined to bed for a twenty-month period. His legs were tapped many times by his physician, who at one time removed 18 liters during a period of twenty-four hours. The chest was tapped three times. Salyrgan and other diuretics were given effectively. About one year before this admission the patient had improved somewhat and was able to sit around the house. He had had an abdominal tap about every two weeks during the previous year and had taken 3 gr. of digitalis a day (recently, 7½ gr. a day).

Physical examination showed that the heart was still greatly enlarged. The rate was variable; at times it was 60 and then quite suddenly jumped to somewhat over 80, with some extrasystoles. The sounds were poor, and no murmurs were heard. There were rales at the lung bases, and signs of fluid at the left base and in the abdomen. The liver was felt 11 cm. below the right costal mar-

*On leave of absence.

gin. There was tremendous porky edema of the legs, and considerable congestion of the neck veins.

The blood pressure was 130 systolic, 65 diastolic.

The red-cell count was 5,480,000, with 80 per cent hemoglobin, and the white-cell count 11,800, with 86 per cent neutrophils. The serum protein was 7.3 gm. per 100 cc. An abdominal paracentesis yielded 6000 cc. of clear, straw-colored fluid. A left chest tap at the angle of the scapula in the seventh interspace yielded bloody fluid, which continued to be bloody and later became xanthochromic.

A chest roentgenogram showed marked enlargement of the heart involving all chambers, most marked in the region of the left ventricle. The right border had a double contour, probably owing to prominence to the right of the left auricle. The posterior mediastinum was also obliterated by auricular enlargement. The pulsations of the heart were extremely weak and diffuse fluoroscopically. When the patient was placed in a prone position the mediastinal shadow changed, becoming broader across the base. The aorta was of normal size. There was considerable air in the left pleural cavity. The left lung seemed about one quarter collapsed. There was also fluid in the left pleural cavity, the level being at the eighth rib in the anterior axillary line. The hilar shadows on both sides were grossly increased in width and density. There was a calcified lymph node in the right axilla. The electrocardiogram continued to show left bundle-branch block.

On the eleventh day a friction rub was heard at the apical area that was confined to diastole and did not disappear on full inspiration. The following day the rub was to-and-fro, being distinct in diastole and systole.

The patient responded to digitalis and diuretics and was discharged on the fifteenth hospital day.

Third admission (four and a half years later). After leaving the hospital the patient remained in bed for about six months but then was able to get up and around; he became very dyspneic on exertion although no more so than formerly. He always had to sleep on several pillows at night. During this interval he frequently accumulated fluid, which was controlled fairly well by diuretics of one sort or another. Three weeks before re-entry he began having a cough productive of white frothy sputum; his legs began to swell, and the dyspnea became so severe that he re-entered the hospital.

Physical examination showed a pale, orthopneic man with labored respirations. There were di-

minished voice sounds, breath sounds and dullness over the left chest anteriorly and posteriorly. The apex impulse of the heart was not seen or felt. The left border of dullness was not made out. The aortic second sound was equal to the pulmonic. The heart sounds were of poor quality, with a rate of 40 at both apex and wrist; the rhythm was normal. There was heavy pitting edema with elephantiasis of both legs.

The blood pressure was 140 systolic, 80 diastolic. The pulse was 40, and the respirations 28.

The red-cell count was 4,800,000, with 90 per cent hemoglobin. The total protein was 6.79 gm. per 100 cc., with an albumin-globulin ratio of 1.54. An electrocardiogram showed a 2:1 block, with left bundle-branch block and left-axis deviation.

A chest roentgenogram showed marked change in the appearance of the heart. It had definitely increased in size, particularly in the region of the superior portion of the right ventricle, with the formation of a localized bulge in this area. There was fluid in the left chest, and slight displacement to the right.

The patient again responded well to digitalis and diuretics and was discharged in three weeks.

Fourth admission (fourteen months later). The patient returned for symptomatic relief of congestive failure.

Physical examination showed a pale man with rather marked respiratory difficulty sitting up in bed. There were moist rales, increased dullness and absent breath sounds over the left chest, both anteriorly and posteriorly, and medium moist rales over the right base. There were no further changes in the examination of the heart. The liver was felt four fingerbreadths below the costal margin. There was elephantiasis of both legs.

The blood pressure was 105 systolic, 55 diastolic.

The red-cell count was 5,030,000, with 92 per cent hemoglobin, and the white-cell count 9200.

A chest roentgenogram showed fluid in the left pleural cavity displacing the heart to the left. The left border of the heart was incompletely visualized. An electrocardiogram showed auricular fibrillation, with complete block and right bundle-branch block.

The patient remained in the hospital for three weeks, on restricted fluids and diuretics, and lost 37 pounds of fluid.

Fifth admission (six months later). At home he continued to take digitalis but diuretics were administered with difficulty because of his poor veins. He had received not more than three intravenous administrations of Salyrgan in the interval and had been reduced to the rectal and intramuscular

use of this drug. He gradually accumulated a large amount of fluid and became much more dyspneic, even at rest.

Physical examination had not changed appreciably. There were marked ascites and peripheral edema. The heart rate was 40 and there were signs of pleural effusion on the left. An electrocardiogram showed auricular fibrillation with complete auriculoventricular block and left bundle-branch block, the ventricular rate equaling 40.

A chest roentgenogram showed that the heart had not appreciably changed. There was slightly more fluid in the left chest than previously and the pulmonary vessels appeared more engorged. There was the marked thickening of the pleura on the left that had been present on all the previous films. Fluoroscopy showed that the right ventricle was still unusually large in its upper portion.

On a regime of bed rest, digitalis, ammonium chloride and Salyrgan, the patient improved rapidly and lost 40 pounds of fluid. He was discharged in three weeks.

Final admission (two and a half years later, at the age of fifty-four). The patient was followed at home by his physician, receiving digitalis, ammonium chloride and Mercupurin, and did well under this regime until two months before admission, when he gradually began to retain fluids and developed increasing edema of the legs and breathlessness. Five days before entry he developed cough productive of pink, frothy sputum, and on the night before admission he became so orthopneic that he was unable to sleep and thought he was going to smother to death.

Physical examination showed a pale, extremely dyspneic man in marked congestive failure. The neck veins were markedly distended in the upright position. The chest was barrel shaped, with flatness to percussion and absent breath sounds in the lower left chest. On the right there were coarse, bubbling rales at the base. The heart was enlarged to the anterior axillary line, the sounds were distant, the rhythm was very irregular, but no murmurs were heard. The abdomen was distended and tympanic. The liver was not enlarged to percussion and the spleen was not palpable. The peripheral edema extended to the groin.

The blood pressure was 105 systolic, 56 diastolic. The apex rate was 76.

The red-cell count was 5,150,000, with a hemoglobin of 16 gm., and the white-cell count 33,400, with 92 per cent neutrophils.

The patient failed to respond to the usual measures and died approximately twenty-four hours after admission.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM W. BECKMAN: In spite of the fact that many features of this case confused me when I went over it, I am relatively certain, because of the symptoms of dyspnea and edema, the physical signs of enlarged heart confirmed by x-ray and the electrocardiographic evidence of increasing conduction difficulty, that the patient was suffering from heart disease and, of course, that he had congestive failure. Dr. Paul D. White always teaches that one is supposed to make not only a functional diagnosis, which would be congestive failure, but also a diagnosis of the structural abnormality of the heart and of the etiology or the condition producing the structural and functional abnormalities.
